# GROUNDWATER RESOURCES OF DELAWARE COUNTY, PENNSYLVANIA

by

Wayne T. Balmer and Drew K. Davis

## ABSTRACT

Delaware County, Pa., is a densely populated area that has limited water resources. The county lies mostly in the Piedmont physiographic province, which is characterized by gently rolling hills, and partly in the Atlantic Coastal Plain physiographic province, which is characterized by a relatively flat landscape. The bedrock consists of metamorphic and igneous rocks. Thin terrace and unconsolidated deposits, characteristic of the coastal plain, cover approximately 28 percent of the county.

Groundwater occurs mostly in the weathered zone above bedrock and in fractures to depths of about 300 feet below land surface. The amount of groundwater that goes into storage annually equals approximately half of the amount of annual precipitation. About 62 percent of the water distributed by public water suppliers is imported from sources outside the county.

The Wissahickon is the most productive water-bearing formation, although the median yield is only 20 gallons per minute. The ultramafite has a median yield of 18 gallons per minute, and the other crystalline units have median yields of 10 gallons per minute or less. The unconsolidated deposits are too thin to support major water withdrawals. None of the geologic formations in Delaware County yield enough water consistently for large public or industrial supplies; however, most wells should produce sufficient quantities for domestic purposes. Water quality is generally suitable for most uses except where manganese and iron are present in water from wells in the Wissahickon Formation, and where groundwater has been locally contaminated.

## INTRODUCTION

### PURPOSE AND SCOPE

This report is part of a continuing program conducted by the U.S. Geological Survey, Water Resources Division, in cooperation with the Pennsylvania Department of Conservation and Natural Resources,

Bureau of Topographic and Geologic Survey, to investigate the water resources of Pennsylvania. Its purpose is to summarize the geohydrology and groundwater resources of Delaware County, Pa. The scope of this report includes descriptions of the geology; hydrology; the occurrence, movement, availability, and chemical quality of the groundwater in the geologic units of Delaware County; and the potential of those units as groundwater sources.

## DESCRIPTION OF STUDY AREA

Delaware County encompasses an area of 185 square miles in the southeastern corner of Pennsylvania (Figure 1). Most of the county lies within the Piedmont physiographic province except for a narrow belt along the Delaware River that lies within the Atlantic Coastal Plain physiographic province (Figure 2). The Piedmont province is characterized by a gently rolling landscape having a few low hills and ridges. The predominant bedrock units are metamorphic rocks. The Atlantic Coastal Plain province is differentiated physiographically from the Piedmont province by its flatter topography. It is separated from the Piedmont province by the Fall Line, which is marked by a sharp change in elevation, the Piedmont being higher. The majority of Atlantic Coastal Plain deposits have been eroded, leaving metamorphic bedrock partially overlain by the discontinuous Cenozoic deposits (Owens and Minard, 1979) and unconsolidated terrace deposits.

All of Delaware County lies in the Delaware River drainage basin. The major streams flow from the northwest to the southeast across the county and discharge into the Delaware River estuary. Cobbs Creek is part of the northeastern boundary of the county. Brandywine Creek forms the boundary to the southwest and drains into the Christina River at Wilmington, Del., and then into the Delaware River. Only the extreme southwestern corner of the county is drained by Brandywine Creek.

Public water companies supply water to most urbanized communities and draw primarily from surface-water sources. Groundwater use for public supply is

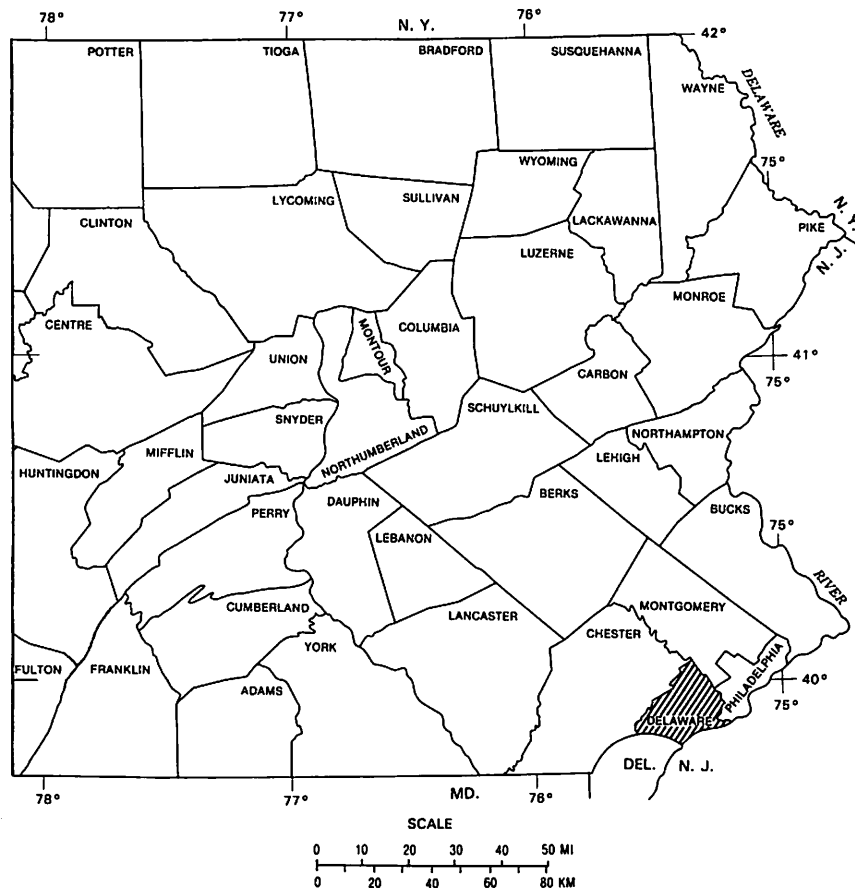

Figure 1. Location of Delaware County.

small. In the more rural areas, homes, farms, and industries rely on wells and springs for their source of supply.

The total population was about 554,000 in 1980, averaging 3,000 people per square mile. The county is highly urbanized and industrialized in the east but is more rural in the west.

### PREVIOUS INVESTIGATIONS

The groundwater resources of Delaware County have been previously studied only in small areas of the county or as part of regional summaries.

Bascom and others (1909) prepared a geologic atlas of the Norristown, Germantown, Chester, and Philadelphia quadrangles that includes text descriptions of the geologic formations. Hall (1934) discussed groundwater in Delaware County as part of his reconnaissance report on southeastern Pennsylvania. Barksdale and others (1958) discussed groundwater resources in the tri-state region adjacent to the Dela-

ware River. Olmsted and Hely (1962) described the relation between groundwater and surface water in the Brandywine Creek basin of Pennsylvania. Water resources for the entire Delaware River basin were summarized by Parker and others (1964). Poth (1968) appraised the hydrogeology of the crystalline rocks of part of northern Delaware County. Owens and Minard (1979) discussed the Bridgeton Formation and the informally named Trenton gravel of the Atlantic Coastal Plain.

### WELL-NUMBERING SYSTEM

The well-numbering system used in this report consists of a county abbreviation followed by a sequentially assigned number. A well having the prefix "De" is located in Delaware County. The wells are listed in numerical sequence in Table 40, and their locations are shown on Plate 1. Gaps in the sequential numbering in the well table reflect a lack of complete records for wells not listed.

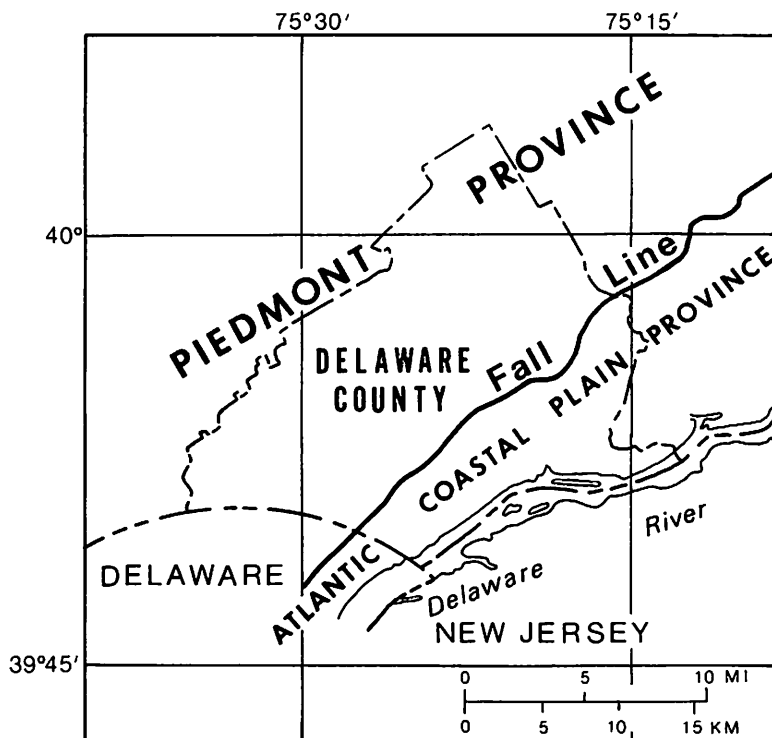

Figure 2. The physiographic setting of Delaware County.

## ACKNOWLEDGMENTS

The authors gratefully acknowledge the cooperation of the homeowners, private industries, municipalities, and state and federal agencies who supplied information and granted access to their properties for the collection of data essential to this study.

## GEOHYDROLOGY

### GEOLOGIC SETTING

The principal geologic units of Delaware County are of Proterozoic, early Paleozoic, Mesozoic, Tertiary, and Quaternary age and are shown on Plate 1. Table 1 contains a brief description of selected units.

#### Crystalline Rocks

The Proterozoic and lower Paleozoic crystalline bedrock consists of gneiss, schist, and other metamorphic rocks. These rocks belong to different geologic terranes that formed separately before being joined to southeastern Pennsylvania by accretion. The complexity of the geology makes age determination difficult for some of the units (see Plate 1). Because the focus of this report is on the hydrologic charac-

teristics of the rock units, crystalline rocks having similar hydrologic characteristics are grouped together as follows for purposes of discussion.

#### Major crystalline aquifers:

- (1) Mafic gneiss—Proterozoic and lower Paleozoic mafic (hornblende-, pyroxene-bearing) gneiss.
- (2) Granodioritic and felsic gneiss—Proterozoic and lower Paleozoic felsic (feldspar-bearing) gneiss, granodioritic gneiss, and granite.
- (3) Wissahickon Formation—schist and some gneiss.

#### Minor crystalline aquifers:

- (1) Ultramafite—lower Paleozoic metamorphic rock derived from the alteration of ferromagnesian silicate minerals such as pyroxene and olivine.
- (2) Anorthositic gneiss—lower Paleozoic plagioclase-feldspar-bearing metamorphosed igneous rock.

Numerous other rock units crop out in Delaware County but are too limited in areal extent to be considered important as aquifers. These include the following units:

- (1) Jurassic diabase, commonly present as dikes and sills.

- (2) Cambrian and Ordovician Conestoga Formation (limestone and some phyllite, mica schist, and limestone conglomerate).
- (3) Cambrian Chickies Formation (quartzite, quartz schist, slate, and conglomerate).
- (4) Lower Paleozoic or Proterozoic Z meta-diorite and pegmatite.
- (5) Lower Paleozoic or Proterozoic Z Cockeysville Marble.
- (6) Octoraro Formation (phyllite), found in a small area at the northern tip of the county. It underlies less than 1 percent of the county.

The most extensive rock unit is the Wissahickon. This formation is predominant throughout the eastern half of the county. There are additional outcrops in the southwestern corner of the county. The Wissahickon Formation crops out over approximately 34 percent of the county and also underlies most of the unconsolidated sediments.

The granodioritic and felsic gneiss units are located mostly in the western and northern parts of the county. They underlie approximately 28 percent of the county. The mafic gneiss units are located mostly in two large areas in the southern and northern parts of the county; many smaller areas are intermingled with the felsic gneisses. Mafic gneiss underlies approximately 11 percent of the county.

Ultramafite predominates in two large areas in the central part of the county and is present as lenses in the granodioritic and felsic gneisses and the Wissahickon Formation. Ultramafite underlies approximately 4 percent of the county.

Anorthositic gneiss is present mostly in a single large area near the border between the county and the state of Delaware. It is also present in smaller areas. Anorthosite underlies approximately 2 percent of the county.

Additional information on these specific geologic units is presented in the section "Major Water-Bearing Formations."

Table 1. *Descriptive Geologic Column and Water-Bearing Characteristics of Selected Delaware County Rock Units*

System or erathem	Geologic unit	Water-bearing characteristics <sup>1</sup>
Quaternary	Trenton gravel (informal usage) (Qt)	Yield range: 8.0–200 gal/min Yield median: 50 gal/min
Tertiary	Bridgeton Formation (Tb)	Not important as a water-bearing formation.
	Bryn Mawr Formation (Tbm)	Not important as a water-bearing formation.
Probably lower Paleozoic and/or Proterozoic Z	Anorthositic gneiss (wan)	Yield range: 1.0–35 gal/min
	Granodioritic and felsic gneiss (gr, Ybfa, Ybfg)	Yield range: 0–100 gal/min Yield median: 10 gal/min Generally soft to moderately hard water.
	Wissahickon Formation (wb, wp)	Yield range: 1.0–300 gal/min Yield median: 20 gal/min Highest yielding crystalline aquifer in county. Generally soft to moderately hard water.
	Mafic gneiss (wbma, wma, pma, Ybma, Ybmg)	Yield range: 0.5–150 gal/min Yield median: 6 gal/min Generally soft to moderately hard water.
	Ultramafite (wum)	Yield range: 2.0–60 gal/min Yield median: 18 gal/min Moderately hard to very hard water.

<sup>1</sup>Definitions for hardness are given on page 24 and in the glossary.

## Unconsolidated Deposits

Unconsolidated deposits overlie the bedrock in approximately 20 percent of the county; they are present mostly in the eastern part bordering the Delaware River. They consist of high-level terrace deposits of Tertiary age, and Quaternary outwash and alluvium deposited on the Atlantic Coastal Plain.

The terrace deposits lie unconformably on crystalline metamorphic rocks. The highest terrace deposits are believed to be Tertiary (Pliocene?) in age and commonly are referred to as the Bryn Mawr Formation (Bascom, 1925). These deposits generally are present at elevations above 300 feet and are less than 20 feet thick.

Terrace deposits between elevations of about 100 feet and 220 feet, some of which were mapped as Pensauken Formation by earlier workers, are assigned to the Bridgeton Formation (Owens and Minard, 1979, p. D13). These deposits are generally less than 20 feet thick. Owens and Minard (1979, p. D18) assigned a late Miocene age to them.

The most recent unconsolidated deposit is the informally named Trenton gravel, which occurs on the Atlantic Coastal Plain. Owens and Minard (1979, p. D38) assigned the Trenton gravel a Sangamonian age. Elevations range between sea level and about 40 feet near the Delaware River estuary and 150 feet further upstream on the tributaries. The thickness of the Trenton gravel generally is less than 20 feet, although it may be as much as 50 feet locally.

The Trenton gravel generally overlies the Wisahickon Formation, except in the extreme northeastern corner of the Delaware County part of the Atlantic Coastal Plain, where it overlies the Cretaceous Raritan Formation. Although the Raritan Formation is about 100 feet thick in this area and is a very high-yielding aquifer, it is not described in this report because (1) it does not crop out in Delaware County, (2) it has not been tapped by wells in the county, and (3) it thins rapidly to the southwest and is present under a very small area of the county.

All of the unconsolidated deposits are discontinuous. The Bridgeton and Bryn Mawr Formations are unimportant as water-bearing formations. They do, however, provide additional recharge and storage for the crystalline rocks beneath them. In this report, data for wells in unconsolidated deposits refer exclusively to the Trenton gravel. Lithologic and hydrologic information for the Trenton gravel is given in the section "Major Water-Bearing Formations."

## HYDROLOGY

A network of 13 observation wells (Figure 3) was established to collect water-level data for all of the geologic units. These data were used to show water-level fluctuations and, in conjunction with surface-water data, to determine a relation between ground-water and surface water.

Streamflow data were obtained from the stream-gaging stations shown in Figure 3. All analyses of streamflow are based on records for water years (October 1 through September 30) unless otherwise noted. Precipitation and temperature data are from the National Oceanic and Atmospheric Administration (NOAA) stations at Chadds Ford, Marcus Hook, and Philadelphia Airport. Precipitation, temperature, and streamflow data were used to calculate base flow, evapotranspiration, and groundwater discharge to streams. Dry, normal, and wet years, used in hydrologic analyses, were selected based on precipitation data from these stations.

## Groundwater

### *Occurrence*

The usefulness of a rock unit as a water-bearing formation depends on the characteristics and structural properties of the rock. Rocks near the surface of the earth are composed of solids (grains) and voids. Voids in the rock consist of intergranular spaces (primary porosity) or joints and fractures (secondary porosity), as shown in Figure 4. Groundwater is present in and moves only through these voids. Most of the water in the consolidated rocks is present in and moves through secondary openings. Primary porosity is found only in the Tertiary and Quaternary deposits and in the weathered zone above consolidated rocks. The groundwater reservoir is the saturated zone below the land surface.

Most groundwater moves from recharge areas, where precipitation infiltrates the ground on uplands and hillsides, to nearby valleys, where it discharges to streams. Streams in the county generally act as drains for the groundwater reservoir. Although deep interbasin groundwater flow may occur, it is probably negligible in this geohydrologic setting.

### *Recharge*

The groundwater recharge to a basin is equal to the base flow of streams draining it if the storage is constant and consumptive use is negligible. Groundwater recharge rates were calculated from hydrograph separations for the Chester, Darby, and Cobbs

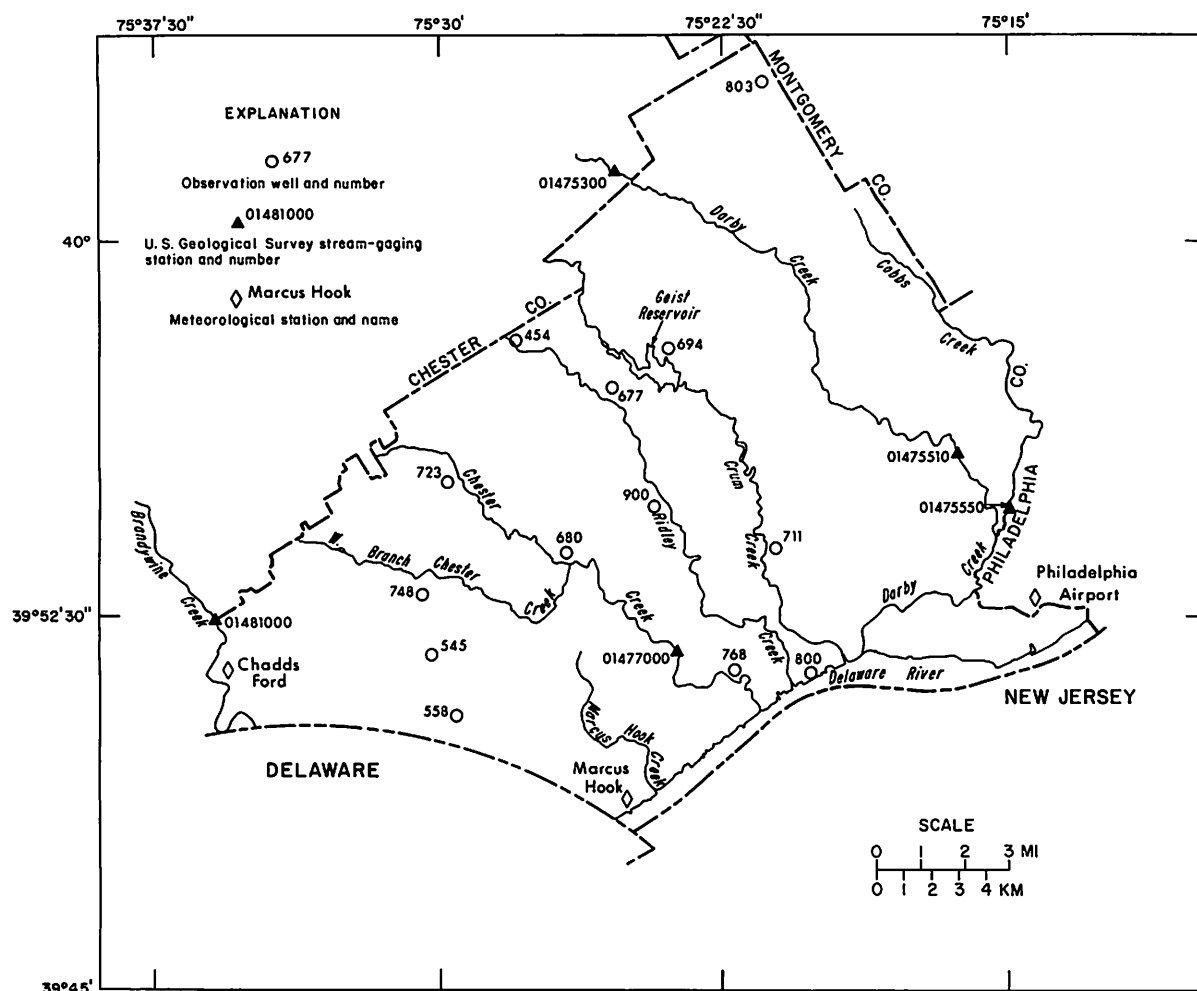

Figure 3. Major streams, stream-gaging stations, meteorological stations, and observation wells in Delaware County.

Creek basins. The Chester and Darby Creek basins lie in Delaware and Chester Counties. The Cobbs Creek basin is highly urbanized in parts of Delaware, Montgomery, and Philadelphia Counties. Dry, wet, and normal years were selected based on the driest and wettest years and the year most closely resembling the 30-year precipitation normal for the three precipitation stations. Recharge rates are given in thousands of gallons per day per square mile in Table 2. The average recharge rate for Delaware County is estimated to be 684,000 (gal/d)/mi<sup>2</sup> (gallons per day per square mile).

Table 2 shows that wetter years have larger recharge rates, although the increase in recharge is not directly proportional to the increase in discharge or precipitation. Cobbs Creek basin, the most highly urbanized area, has the least amount of recharge of

the three basins. Recharge rates for the two gages on Darby Creek were calculated for the corresponding areas of the basins measured by each gage. The upper reach of Darby Creek had a greater recharge rate than the entire basin, probably because urbanization is low in the upper reach.

### Weathering

The weathering process is a mechanical and chemical breakdown of rock by the actions of air, water, temperature variations, and biological activity. The process is most intense near the land surface and usually decreases as depth increases. The top of consolidated rock is the lower limit of the weathered zone. Below this zone the rock is generally solid, but some weathering extends farther, particularly along frac-

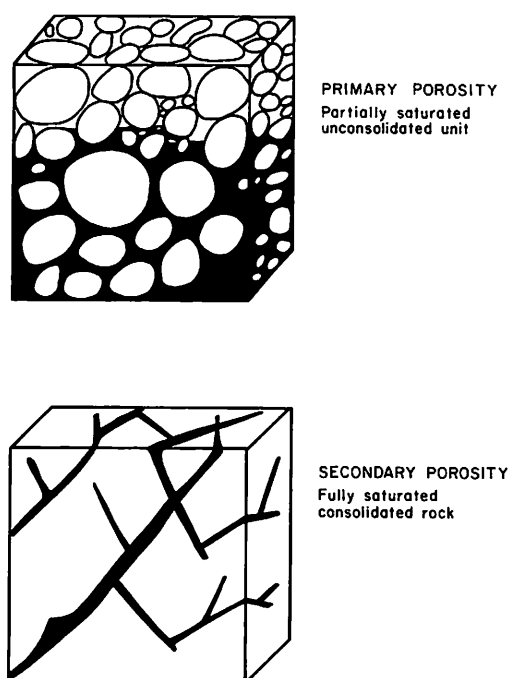

Figure 4. Schematic illustrations of primary and secondary porosity (modified from Heath, 1983).

tures. The change in the rock with depth is gradational, ranging from soil at the surface, to unconsolidated clay and bits of rock, to boulder-sized rock in a clayey matrix. The storage capacity and permeability of the weathered rock vary according to the nature of the parent rock, degree of weathering, and the filling of joints and pores by clays and chemical precipitates. Water in the weathered zone is stored in and moves through both primary and secondary openings.

Casing in drilled wells prevents loose material from collapsing into the borehole. The loose material consists of unconsolidated deposits or the soil and rock fragments that comprise the weathered zone above solid bedrock, so that the casing is commonly set a few feet into solid bedrock. As a result, the depth of the weathered zone can be estimated, but not determined precisely, from casing depth. Depth of casing and median depth to water are given in Table 3. The median depth of weathering in most units is about 40 feet. Ultramafite, which is very resistant to chemical weathering, has a median depth of well casing of about 60 feet and is an anomaly to the above method of estimation of the weathered zone. This median depth of well casing probably reflects the softness of the rock rather than the depth of the weathered zone.

### Storage

The groundwater reservoir consists of water stored in the saturated zone. Because groundwater discharges to streams, groundwater withdrawals will reduce base flow. All withdrawals lower local groundwater levels. Excessive withdrawals may lead to extensive lowering of levels and the depletion of the groundwater reservoir.

The weathered zone and the unconsolidated deposits are important because they contain a major percentage of the water in storage. Specific yield (the ratio of water that will drain from a volume of rock or soil under the force of gravity to the volume of rock or soil) of the unconsolidated deposits was estimated by Barksdale and others (1958, p. 163) to be 30 percent. This figure was used to calculate the storage of water in unconsolidated deposits in the county. Olmsted and Hely (1962, p. 18) estimated a specific yield of the weathered zone as 7.5 to 10 percent. A conservative estimate of 8 percent for the specific yield of the weathered zone is used in this report. The average saturated thickness of the weathered zone was estimated from the median depth of well casing minus the median depth to water (Figure 5 and Table 3). Based on data for 282 wells, the average estimated saturated thickness for all of the consolidated rock aquifers is 20 feet.

Table 2. Recharge Rates for Darby, Cobbs, and Chester Creek Basins for Dry (1981), Normal (1976), and Wet (1979) Years

Gaging-station name and number	Drainage area (mi <sup>2</sup> )	Type of year	Recharge rate <sup>1</sup>
Darby Creek at Waterloo Mills near Devon 01475300	5.15	Dry Normal Wet	433 881 1,036
Darby Creek near Darby 01475510	37.4	Dry Normal Wet	334 774 856
Cobbs Creek at Darby 01475550	22.0	Dry Normal Wet	271 428 698
Chester Creek near Chester 01477000	61.1	Dry Normal Wet	387 653 940
Average of above stations		Dry Normal Wet	356 684 892

<sup>1</sup>Thousands of gallons per day per square mile.

Table 3. *Median Depth of Well Casing, Median Depth to Water, and Estimated Saturated Thickness of the Weathered Zone for Consolidated Rock Units in Delaware County*

Geologic unit	Number of wells	Median well casing depth or range (feet)	Median depth to water or range (feet below land surface)	Estimated saturated thickness of the weathered zone (feet)
Anorthositic gneiss	6	20-31	7.1-35	10
Granodioritic and felsic gneiss <sup>1</sup>	129	40	—	12
Mafic gneiss <sup>1</sup>	134	—	29	—
	54	40	—	15
	53	—	25	—
Ultramafite	8	62	20	43
Wissahickon Formation <sup>1</sup>	114	40	—	20
	112	—	20	—

<sup>1</sup>One set of wells was used to determine well casing depth and saturated thickness, and a different set was used to determine depth to water.

Storage also occurs in fractures in the upper 300 feet of the consolidated crystalline rocks. These fractures, which serve mainly as pathways for water to move through the rock, have a low storage capacity. The estimated specific yield for this zone is 0.2 percent (McGreevy and Sloto, 1977, p. 33). The approximate volume of water in storage per unit area can be calculated using the above estimates of specific yield and average saturated thickness; total storage is storage per unit area times area:

	Storage (feet of water) <sup>1</sup>	Area (square miles)	Total storage (million gallons)
Weathered zone of consolidated rocks	1.6	143.5	47,900
Unconsolidated units <sup>2</sup>	4.5	36.5	34,300
Unweathered zone of consolidated rocks	.6	180	22,500
<b>Total</b>			<b>104,700</b>

<sup>1</sup>Cubic feet of water per square foot of aquifer.

<sup>2</sup>Includes any water stored in the weathered zone of consolidated rocks beneath the unconsolidated units.

Thus, the average amount of water in storage for the entire county is about 2.5 feet (30 inches).

### Groundwater Levels

The groundwater system in Delaware County is dynamic. The groundwater level is constantly rising and falling as a result of various stresses affecting this system, such as climatic conditions and withdrawals. Water levels have a seasonal trend, generally rising during the nongrowing season (winter and early

spring), when evapotranspiration is low, and declining during the growing season (late spring, summer, and early fall), when evapotranspiration is high. Hydrographs for two wells, De-800 and De-748, are shown in Figure 6. Well De-800 is in the Wissahickon Formation and is on the floodplain of the Delaware River. Well De-748 is on a hillside in the felsic gneiss near an unnamed tributary to Chester Creek. These hydrographs show the variation in seasonal water-level fluctuation and the typical range of fluctuation.

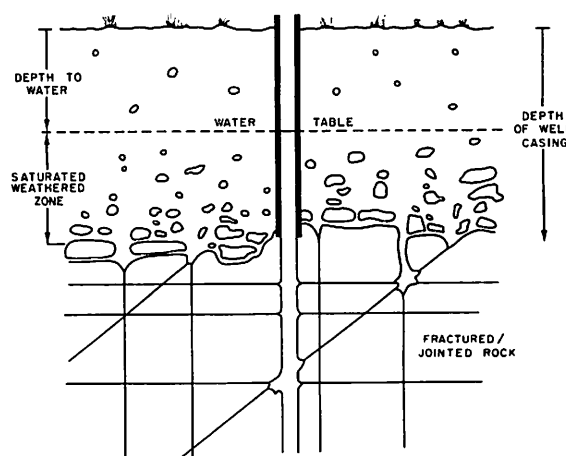

Figure 5. The saturated thickness of the weathered zone, estimated by subtracting the depth to water from the depth of well casing (illustration modified from McGreevy and Sloto, 1977).

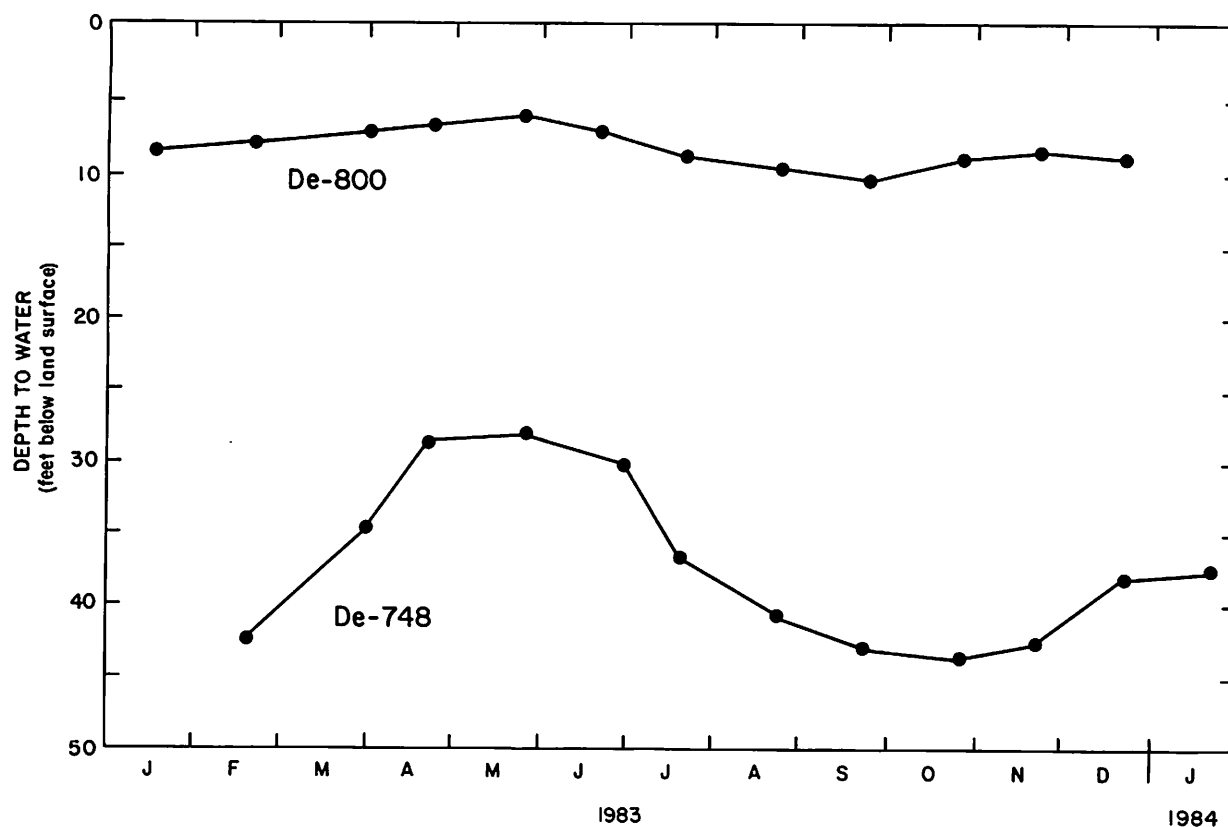

Figure 6. Hydrographs illustrating water-level fluctuation in two wells from January 1983 to January 1984. Well De-800 is in the Wissahickon Formation on the floodplain of the Delaware River. Well De-748 is in felsic gneiss on a hillside near a tributary of Chester Creek.

The amplitude of water-level fluctuation depends on several conditions. A comparison of well locations and annual water-level fluctuations is given in Table 4. Wells in a floodplain or close to a stream or discharge point generally tend to have small seasonal variations and shallow depths to water. Wells distant from a stream generally have high seasonal fluctuations and greater depths to water (Figure 7).

The water table near the Delaware River estuary fluctuates in response to tides. The amplitude of these fluctuations decreases with distance from the estuary. In a well, tidal fluctuation is induced by the change in hydraulic gradient of the water table caused by the change in river level during the tidal cycle. There is a time lag between the cycles in the estuary and the cycles in the aquifer; this time lag increases with distance from the estuary. Tidal effects are most pronounced in the unconsolidated deposits, which can transmit gradient changes over long distances because of high hydraulic conductivity (the ability of a rock to transmit water). Wells in the unconsolidated deposits in close proximity to the Delaware estuary

that show a strong tidal influence may be susceptible to saltwater encroachment during heavy pumping.

### Surface Water

Four of the major streams in Delaware County drain directly to the Delaware River; these are Darby, Ridley, Crum, and Chester Creeks. Cobbs Creek is a tributary to Darby Creek. Darby and Cobbs Creeks are not used as a source of water supply in Delaware County because of limited quantity and poor quality, the latter term signifying water that is unsuitable for human consumption and most other uses. Two municipal wastewater treatment plants that discharge into tributaries of Chester Creek upstream of Delaware County significantly reduce its quality. In 1983, the dissolved mercury concentration measured at East Branch Chester Creek below Goose Creek near West Chester in Chester County (gaging station 01476848) was 110  $\mu\text{g/L}$  (the U.S. Environmental Protection Agency [USEPA] recommended limit for drinking water is 2  $\mu\text{g/L}$ ), and the dissolved nitrate as nitro-

Table 4. Comparisons of Well Locations With Annual Water-Level Fluctuations

Well number	Geologic unit	Topographic location	Range (feet)	Water level	
				High (feet below land surface and month)	Low (feet below land surface and month)
De- 800	Wissahickon Formation	Floodplain along the Delaware River	4.21	6.06 May	10.27 Sept.
711	Mafic gneiss	Floodplain of Crum Creek	4.31	4.80 May	9.11 Aug.
545	Wissahickon Formation	Hilltop near tributary to South Creek	5.64	21.38 June	27.02 Nov.

558	Mafic gneiss	Hillside near West Branch of Naaman Creek	7.98	25.34 May	33.32 Nov.
680	Felsic gneiss	Hilltop near Chester Creek	11.33	21.90 Apr.	33.23 Sept.
748	do.	Hillside near tributary to Chester Creek	15.47	28.12 May	43.59 Oct.

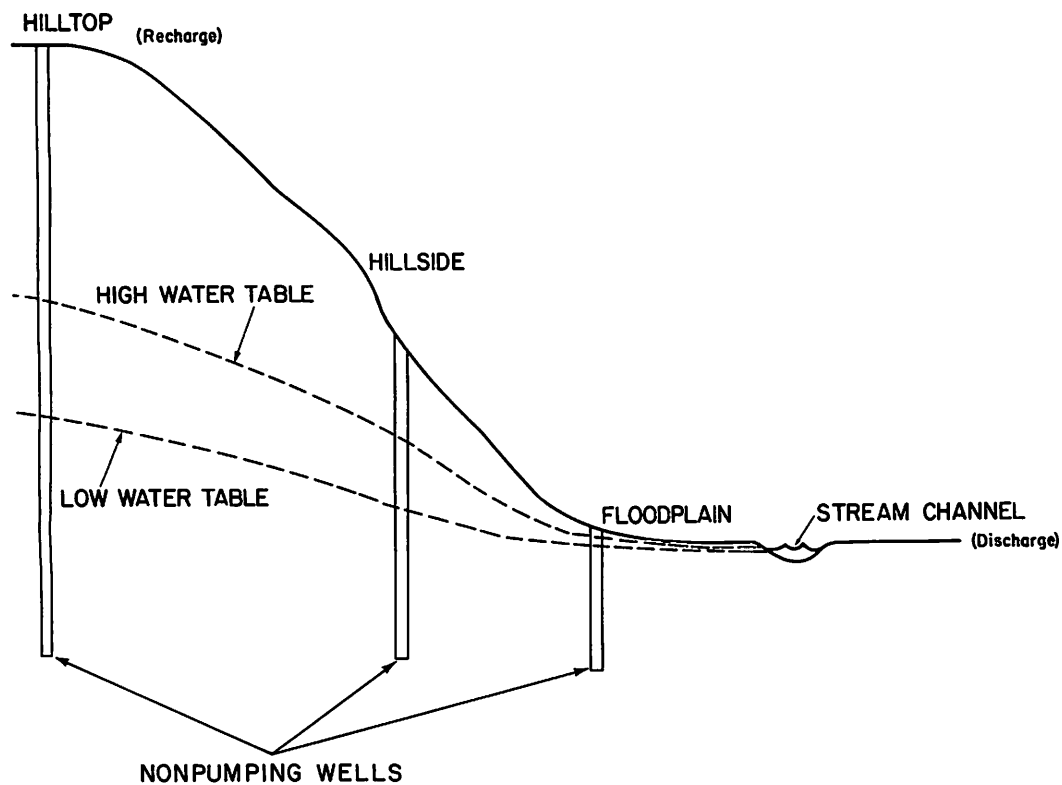

Figure 7. Variability of the water table with distance from point of discharge.

gen concentration was 27 mg/L (the USEPA recommended limit is 10 mg/L). Many industries and institutions, as well as the boroughs of West Chester and Downingtown and the city of Coatesville, discharge wastewater into Brandywine Creek. Based on weekly samples, fecal coliform bacteria concentrations exceeded the criteria for drinking water 100 percent of the time in 1983. Downstream from Delaware County, Brandywine Creek supplies the city of Wilmington, Del., and its surrounding area.

### Discharge

Streamflow is a combination of direct runoff from precipitation and base flow. Base flow is groundwater discharge to streams. Streamflow data are available for at least 10 years of record for the five gaging stations shown in Figure 3. The length of record for each station is listed in Table 5. Discharge hydrographs were separated into base flow and direct-runoff components for the period of record for the following stations: Darby Creek at Waterloo Mills near Devon (01475300), Darby Creek near Darby (01475510), Cobbs Creek at Darby (01475550), Chester Creek near Chester (01477000), and Brandywine Creek at Chadds Ford (01481000). Hydrograph separations were done using a model by Pettyjohn and Henning (1979). Table 6 shows comparisons between the streamflow (discharge) and base flow of the five stations. The data in Table 6 are useful in evaluating streams as a potential water supply. The more consistent the base flow remains during various conditions and the higher the proportion of base flow to streamflow, the more reliable the stream is as a water source. Cobbs Creek has the lowest ratio of base flow to streamflow of the five streams. A lower ratio proba-

bly is caused by increased direct runoff from storm sewers in highly urbanized areas. The high amount of impervious surface in such an area causes more precipitation to become direct runoff and less to become groundwater recharge. Therefore, less water is available to be discharged as base flow. The gages in more rural settings, Darby Creek at Waterloo Mills near Devon and Brandywine Creek at Chadds Ford, show higher ratios of base flow to streamflow than the gages in more urban areas.

Table 7 shows a comparison of the precipitation, total discharge, and base-flow discharge at the two stream gages on Darby Creek for 1973 through 1982. Streamflow data for Darby Creek show a lower percentage of base flow at the downstream station (Darby Creek near Darby) than at the upstream station (Darby Creek at Waterloo Mills near Devon), which drains a more rural area. Possible reasons for the lower percentage of base flow are more rainfall in the upper part of the basin and more direct runoff because of urbanization in the lower part of the basin.

### Flow Duration

Differences in physical characteristics and climatic conditions of basins will cause differences in streamflow. The variability and magnitude of streamflow are dependent upon variables such as basin size, slope, shape, elevation, geology, ground cover, and stream density, as well as climatic conditions. These differences can be shown by flow-duration curves of the streamflow. A flow-duration curve shows the percentage of time a rate of discharge is expected to be equaled or exceeded during a given period.

The shape of the flow-duration curve reflects the characteristics of the drainage basin. The high-flow

Table 5. Lengths of Records for Stream-Gaging Stations

Gaging-station name	Gaging-station number	Drainage area (mi <sup>2</sup> )	Years of record	Period of record (water years)

	Normal	19.91	13.73	69
	Wet	37.38	19.75	53
Brandywine Creek at Chadds Ford 01481000	Dry	9.41	6.40	68
	Normal	19.78	14.71	74
	Wet	32.57	18.47	57

<sup>1</sup>Cubic inches of water per square inch of basin area.

end of the curve is related to climate, topography, and land cover (runoff features), whereas the low-flow end (base flow) is related to the geology of the basin. A curve that is steep throughout indicates the flow of

a highly variable stream that is characterized by much direct runoff. A flat curve indicates the availability of enough surface-water or groundwater storage in the basin to moderate streamflow.

Table 7. *Comparison of Precipitation, Total Discharge, and Base-Flow Discharge for Darby Creek at Waterloo Mills Near Devon and Darby Creek Near Darby, 1973–82*

<sup>1</sup>Precipitation measured at the Devault and Conshohocken stations.<sup>2</sup>Cubic inches of water per square inch of basin area.<sup>3</sup>Precipitation measured at the Philadelphia Airport.

Figure 8 shows flow-duration curves for four streams in Delaware County. Discharge is given in units of cubic feet per second per square mile of drainage basin. Comparison of runoff on this basis eliminates basin size as a factor, thereby better demonstrating the combined influences of climate, geology, topography, and man-made structures on stream-flow. Cobbs Creek near Darby has the lowest discharge per square mile of these four streams. As Darby Creek at Waterloo Mills near Devon has the lowest percentage of time that the higher discharges were equaled or exceeded, it has the least tendency for flash flooding. This is probably because it drains a more rural area than the other streams.

Table 8 shows the duration of daily discharge, in cubic feet per second per square mile of drainage basin. Chester Creek near Chester has the highest

discharge. Part of this flow is attributable to the discharges of two municipal sewage treatment plants upstream. Their effluent largely represents groundwater withdrawals by public water suppliers in Chester County and interbasin transfers from the Ridley and Brandywine Creek basins. Cobbs Creek shows both a high frequency of high-discharge events (flash floods) and a high frequency of lower discharge when compared to the other stations, primarily because of the large impervious area caused by urbanization in the Cobbs Creek basin.

### Relation Between Groundwater and Surface Water

Groundwater levels influence the surface-water base flow, thereby sustaining from 40 to 80 percent of

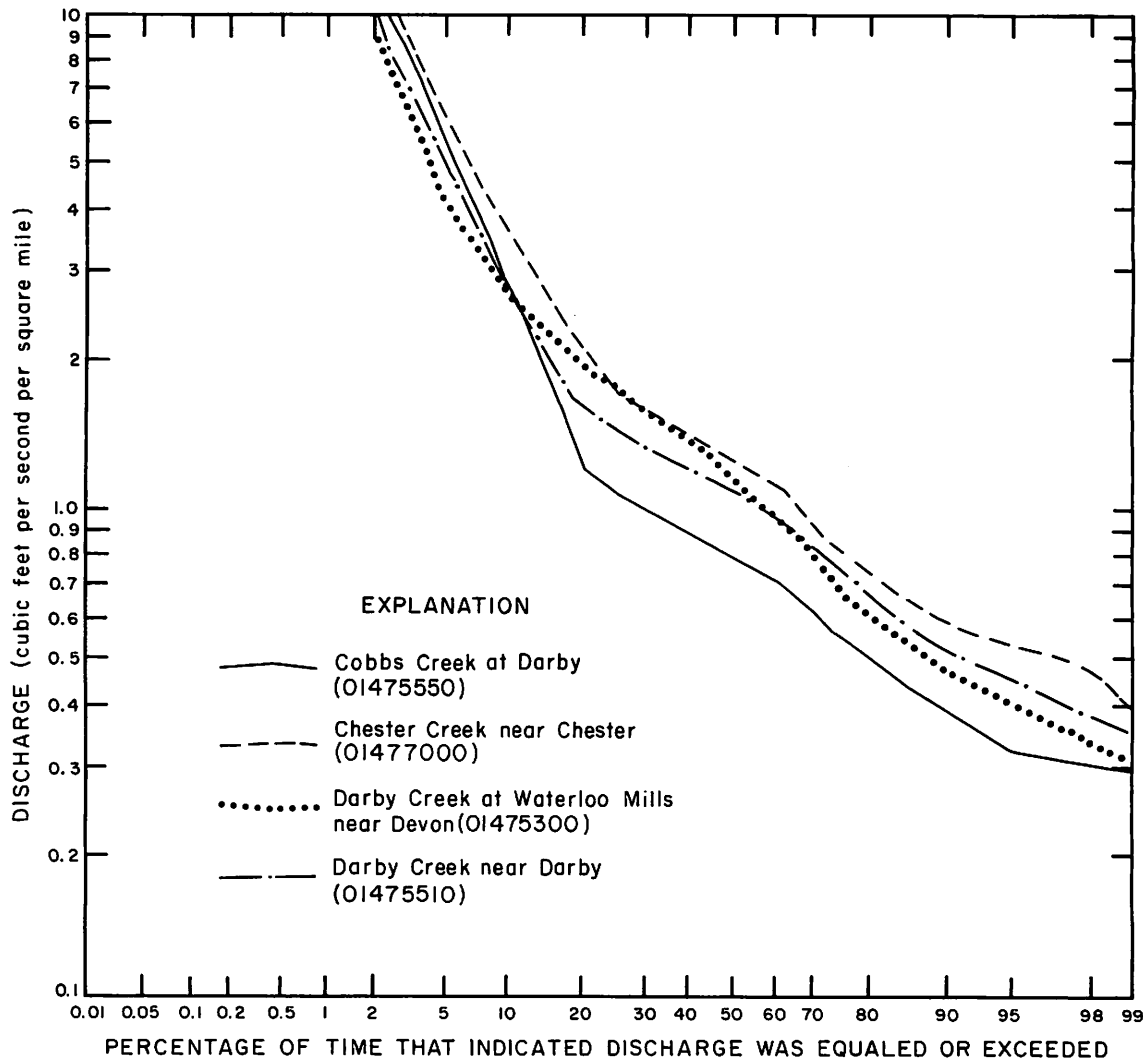

Figure 8. Flow-duration curves of daily discharge for selected streams, 1979-82.

Table 8. Duration of Daily Discharge at Four Gaging Stations

Gaging- station name and number	Drainage area (mi <sup>2</sup> )	Discharge in cubic feet per second per square mile of drainage area that is equaled or exceeded for the indicated percentage of time												
		2	5	10	20	30	40	50	60	70	80	90	95	98

the total surface-water flow. Figure 9 shows the streamflow and base-flow hydrographs for Chester Creek near Chester for the 1983 water year and the hydrograph for well De-680 for part of the 1983 water year. Except for floods, stream stages show the same seasonal variations as groundwater levels.

## Water Use

### Public Water Suppliers

Almost 62 percent of the water delivered in Delaware County is imported from groundwater and

surface-water sources in the adjoining counties. Three major public water suppliers and three minor ones supply the county. Supply systems of the three major water companies are interconnected. Figure 10 shows the service areas of the county's six public water suppliers. In areas outside the service areas, water is obtained from private wells. Table 9 shows the average daily water production and sources of public water supply in Delaware County.

The West Mattson Company and Castle Rock Water Association are small, publicly owned, self-supplied systems. The West Mattson Company has

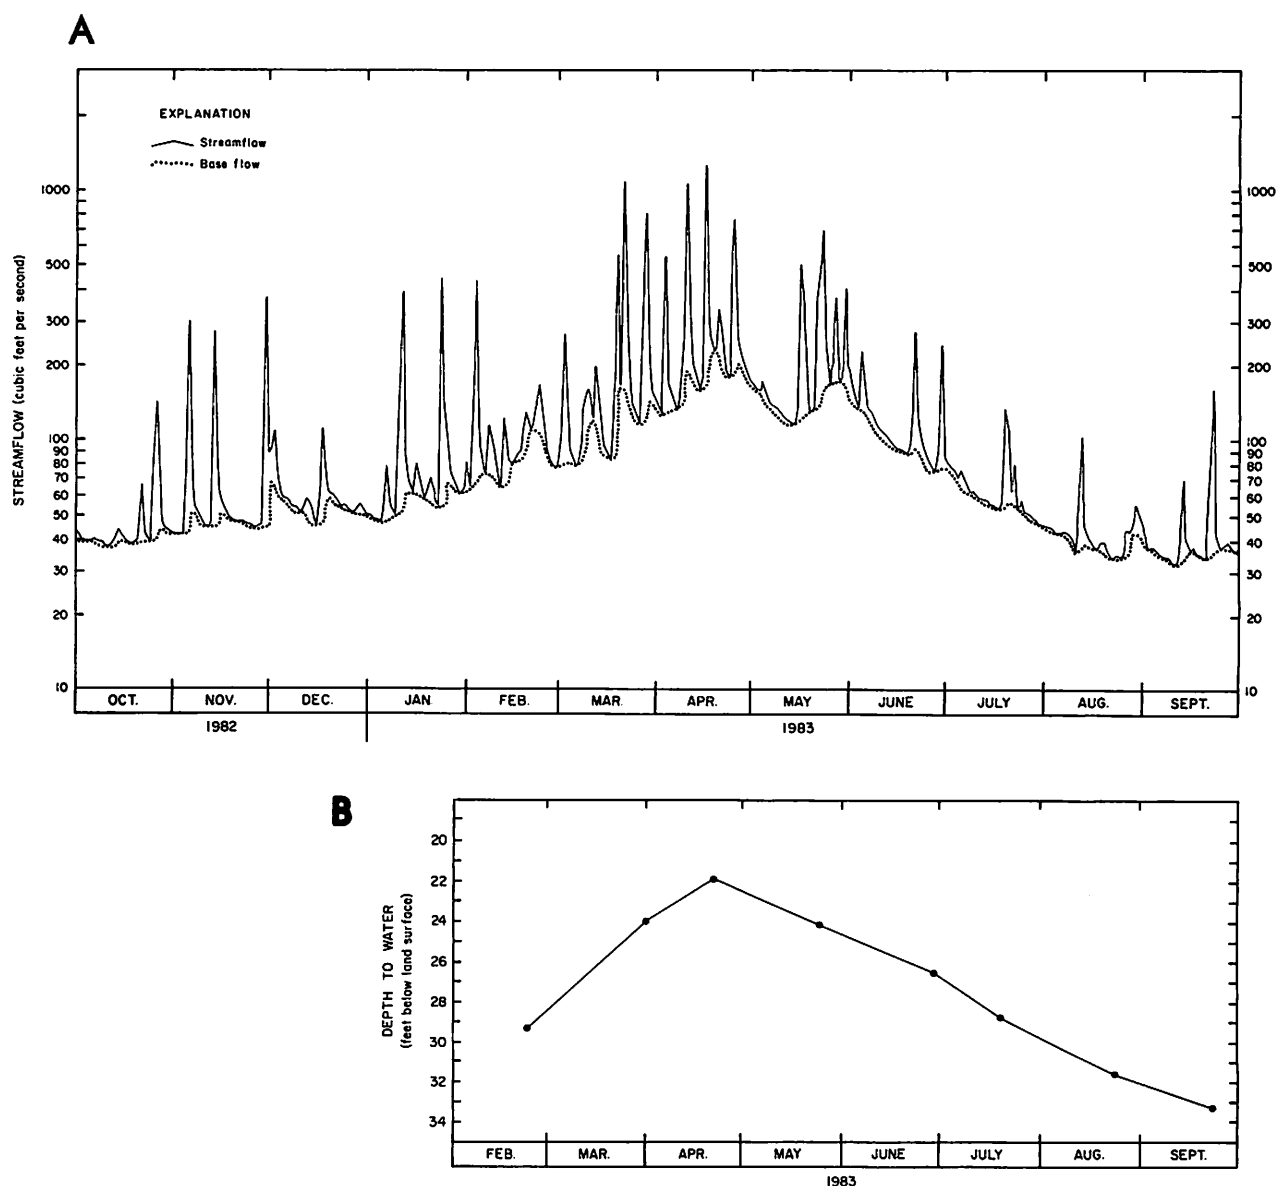

Figure 9. Hydrographs of streamflow and base flow for Chester Creek near Chester (A) and hydrograph for well De-680 (B).

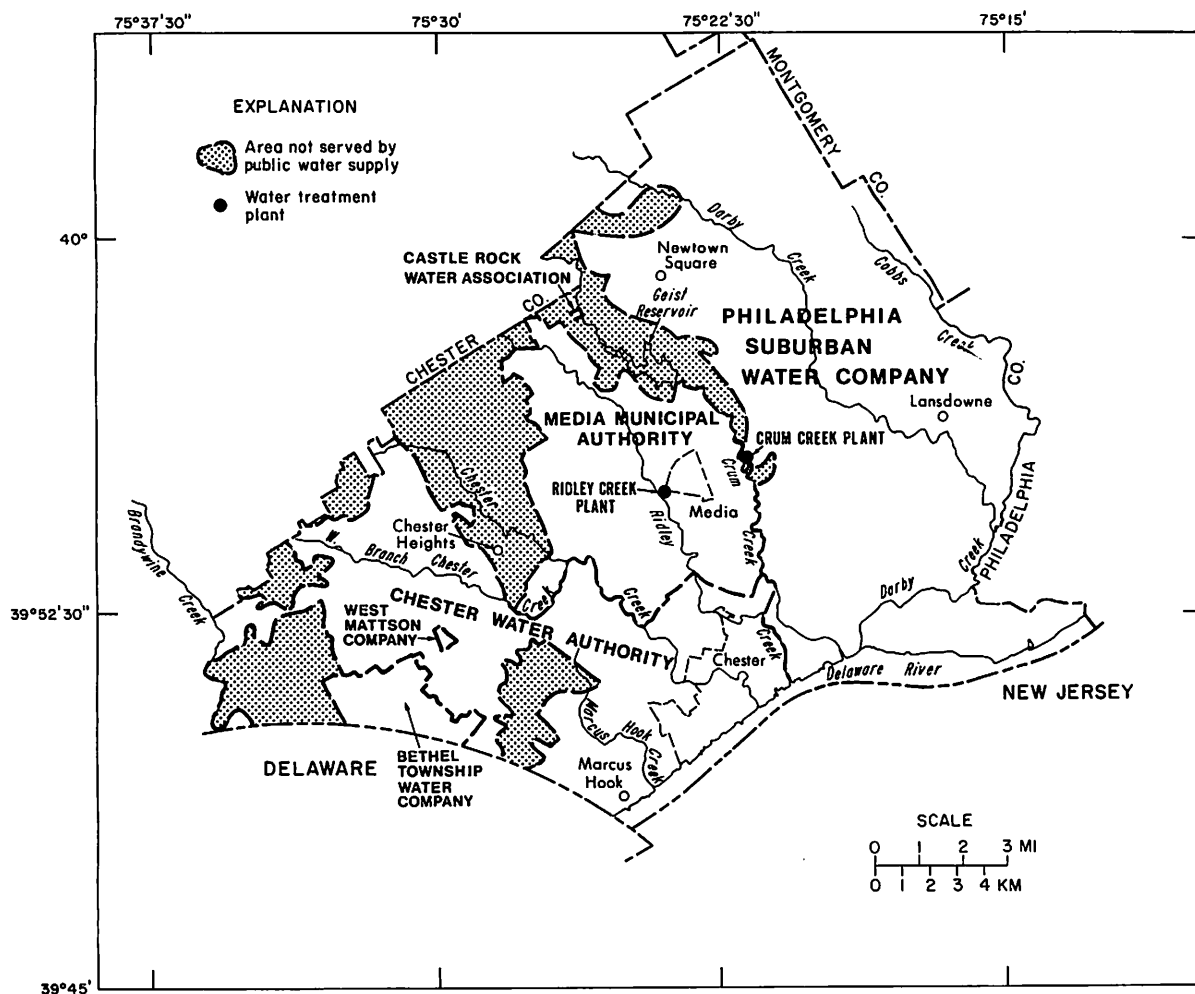

Figure 10. Areas served by public water suppliers in Delaware County.

two wells and supplies 58 connections. The Castle Rock Water Association has one well, and the water use is small but unknown. The Bethel Township Water Company obtains an average of 1.3 Mgal/d from the

Chester Water Authority. It supplies only a few customers in Delaware County and transmits the remainder of the water to the Wilmington Suburban Water Corporation in Delaware.

Table 9. Water Sources of the Public Water Suppliers in Delaware County

Supplier	Sources	Average daily production (Mgal/d)
Bethel Township Water Company	Buys water from Chester Water Authority	1.3
Castle Rock Water Association	1 well	— <sup>1</sup>
West Mattson Company	2 wells	—
Chester Water Authority	Octoraro Creek (outside county)	26.5
	Susquehanna River (outside county)	.059
Media Municipal Authority	Ridley Creek, Chester Creek, and 1 well	4.5
Philadelphia Suburban Water Company	Crum Creek	20
	Pickering Creek, Perkiomen Creek, Schuylkill River, and 16 wells (all outside county)	24

<sup>1</sup>Dashes indicate that average daily production is unknown.

The Media Municipal Authority maintains a surface-water treatment plant on Ridley Creek near Media. This water supply is augmented by water pumped from Chester Creek to the treatment plant. In addition, the authority draws water from one well. The well produces about 0.125 Mgal/d. The authority also imports water from both the Philadelphia Suburban Water Company and the Chester Water Authority. The average sendout from the plant is about 4.5 Mgal/d; however, this fluctuates considerably according to the season. The total surface allocation of the Media Municipal Authority is 3 Mgal/d from Ridley Creek and 3 Mgal/d from Chester Creek.

The Chester Water Authority imports most of its water from a treatment plant below its impoundment reservoir on Octoraro Creek, which forms part of the boundary between Chester County and Lancaster County. To supplement the flow of the Octoraro, the authority maintains a 30 Mgal/d pumping station on the Susquehanna River. This has been used only for testing, having pumped only 21 Mgal during 1983. In 1983, the Chester Water Authority served an estimated population of 103,000 people in Delaware County. The average output of the Octoraro treatment plant was 26.5 Mgal/d; approximately 97 percent of this was supplied to Delaware County.

The Philadelphia Suburban Water Company is the largest water supplier in Delaware County, serving an estimated population of 425,000. The sole source of water within the county that is used by this company is Crum Creek; the average production from that creek is approximately 20 Mgal/d. The company's total supply to the county is about 44 Mgal/d. The additional water comes from 16 wells and a treatment plant on Pickering Creek, which draws water from Pickering Creek, Perkiomen Creek, and the Schuylkill River. These sources are in Chester and Montgomery Counties.

The populations served by public water suppliers and self-supplied through the use of private water wells are as follows:

Supplier	Source	Population
Self	Groundwater	19,587
Public	Groundwater	1,060
	Surface water	534,360
	Total	535,420

In Delaware County, 96 percent of the total population is served by public water suppliers and about 90 percent of the total population is served by public sewers.

### *Water Use From Sources Within the County*

Reported major uses of water from sources within the county are summarized in Table 10. The largest use is thermoelectric power generation, most of which occurs in stream. Industrial use accounts for the greatest withdrawals and consumption within the county. Reported agricultural withdrawals are almost negligible.

### **Water Budget**

#### *Precipitation*

Precipitation is the source of groundwater and surface water in Delaware County. Long-term precipitation data are available from the Philadelphia Airport station, the Chadds Ford station, and the Marcus Hook station. Figure 11 shows the annual and normal precipitation at Marcus Hook. Monthly variability can be up to one order of magnitude and is erratic. The average of the normal precipitation for the three recording stations in and near Delaware County for each month from 1951 through 1980 is shown in Figure 12. Total precipitation is nearly evenly distributed throughout the year. The average of the yearly normals for the three stations is 43.46 inches.

Table 10. *Reported Water Use From Sources Within Delaware County*

(Data from surveys conducted by Pennsylvania Department of Environmental Protection)

Source	Average daily amount (gallons)
<i>Public-supplied domestic (1981)</i>	
Surface water	3,990,000
Groundwater	43,610
Total	4,033,610
Consumption (estimated)	-403,361
Net return to streams	3,630,249
<i>Industrial (1977)</i>	
Surface water	303,508,200
Groundwater	274,430
Total	303,782,630
Consumption	-41,356,585
Net return to streams	262,426,045
<i>Thermoelectric (1977)</i>	
Surface water	1,410,000,000
Consumption	-2,790,000
Net release to streams	1,407,210,000
<i>Agriculture (1977)</i>	
Irrigation	None
Livestock	47,300

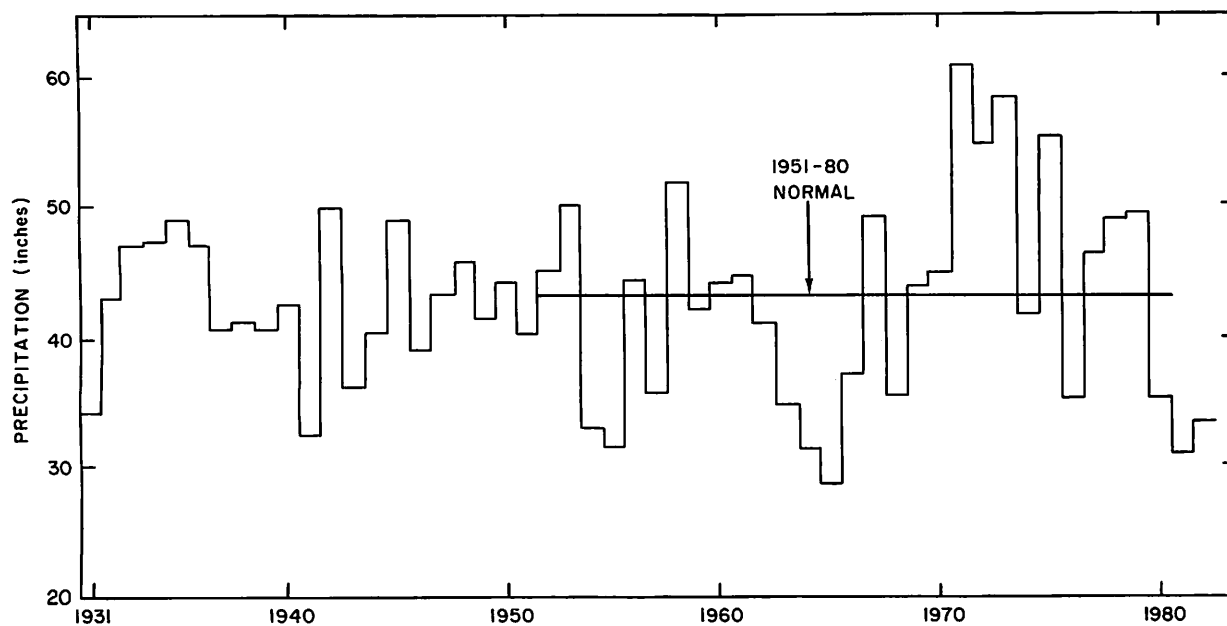

Figure 11. Annual precipitation at Marcus Hook, 1931-82, and the normal precipitation based on that recorded for 1951-80.

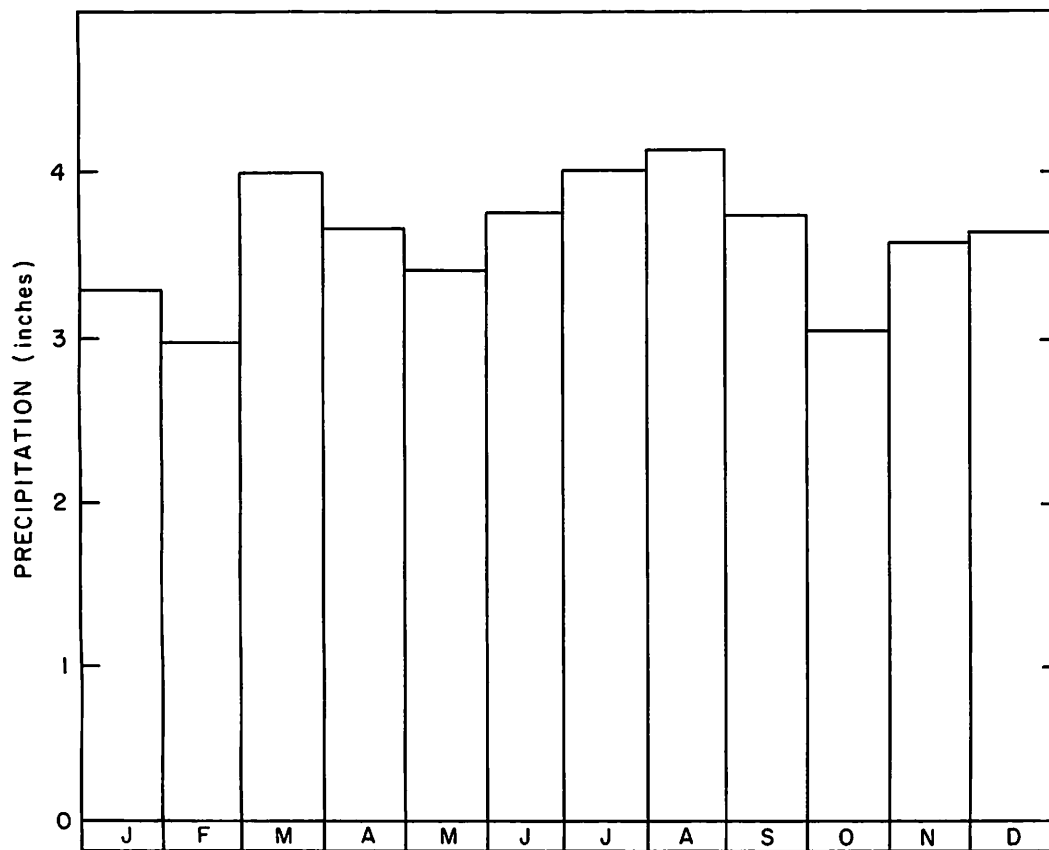

Figure 12. Average of normal monthly precipitation recorded at Chadds Ford, Marcus Hook, and Philadelphia Airport for 1951-80.

Monthly precipitation totals at Chadds Ford, Marcus Hook, and the Philadelphia Airport for 1981-83 are shown in Figure 13, which illustrates both the variability of precipitation at each station within each year and the variability of precipitation between stations.

### *Evapotranspiration*

If enough water is available to supply the needs of plants and to maintain soil moisture at saturation, evaporation from the soil and transpiration by plants proceed at a maximum rate called potential evapotranspiration. The rate of actual evapotranspiration is usually less than the potential rate because potential evapotranspiration usually exceeds the quantity of water available from precipitation. During times of no precipitation, water for evapotranspiration comes from soil moisture. Soil moisture is replenished when precipitation exceeds actual evapotranspiration.

Potential evapotranspiration is related to temperature and was computed using Thornthwaite's equation (Thornthwaite, 1944) and Criddle's adjustment (Criddle, 1958) from temperature data at Marcus Hook for 1981-83. Marcus Hook is the station that most closely approximates the average precipitation and temperature for Delaware County. Mean monthly temperature, precipitation, and potential evapotranspiration are compared in Figure 14. Evapotranspiration varies seasonally. Generally, water surpluses, when precipitation exceeds potential evapotranspiration, occur during the winter months, and water deficits occur during the summer months.

### *Annual Budget*

A water budget is an estimate of water entering and leaving an area, plus or minus changes in storage, during a given period of time. Water enters as precipitation and leaves as streamflow, groundwater underflow, and evapotranspiration, plus or minus changes in groundwater and soil-moisture storage.

A simplified water budget for Delaware County was calculated. If it is assumed that the change in storage is negligible, the water-budget equation is expressed as follows:

$$P = R_d + R_b + ET$$

where

P = precipitation,  
 $R_d$  = direct runoff,  
 $R_b$  = baseflow, and  
 ET = evapotranspiration.

Total runoff was converted to inches of water over the drainage basin. An average percentage of base flow

for the county was calculated from proportional base-flow percentages based on the relative sizes of the drainage basins. Total runoff ( $R_t$ ), in inches of water, can be expressed as follows:

$$R_t = R_d + R_b$$

$$20.43 = 6.73 + 13.70$$

Using the average of the normal precipitation recorded at the three stations and the weighted runoff figures above, the budget equation, in inches of water, can be expressed as follows:

$$P = R_d + R_b + ET$$

$$43.46 = 6.73 + 13.70 + 23.03$$

Because the total water in storage in Delaware County was estimated to be 30 inches, average annual base-flow is equal to about 46 percent of the total volume of water in storage in the county.

## GROUNDWATER RESOURCES

### QUANTITY

#### *Influence of Topography*

Topography is an important factor to consider when drilling a well. Table 11 summarizes well yields, depths to water, and depths of well casings by topographic position. These factors were considered independent of the formation in which the wells are located. Wells drilled in valleys tend to have a higher yield and shallower depth to water than wells located on higher ground. The median depth of casing for all wells, regardless of topographic position, is about 40 feet below land surface.

The median yield of wells in valleys is 30 gal/min, compared with medians of 10 gal/min for both hillsides and hilltops. The range of yields of wells in valleys also is greater than the range of yields of wells in higher topographic positions. These statistics indicate both a greater chance of securing adequate water supplies and more variability in the yields of wells in valleys.

The median depth to water for wells in valleys is 11.1 feet below land surface but is 27.0 feet for hillsides and 34.5 feet for hilltops. Depth to water is least variable and shallowest for wells in valleys.

#### *Depths of Wells*

The depths of drilled wells in the major water-bearing rock units are summarized in Table 12. The Wissahickon Formation has the widest range and the greatest median well depth. Median well depths are

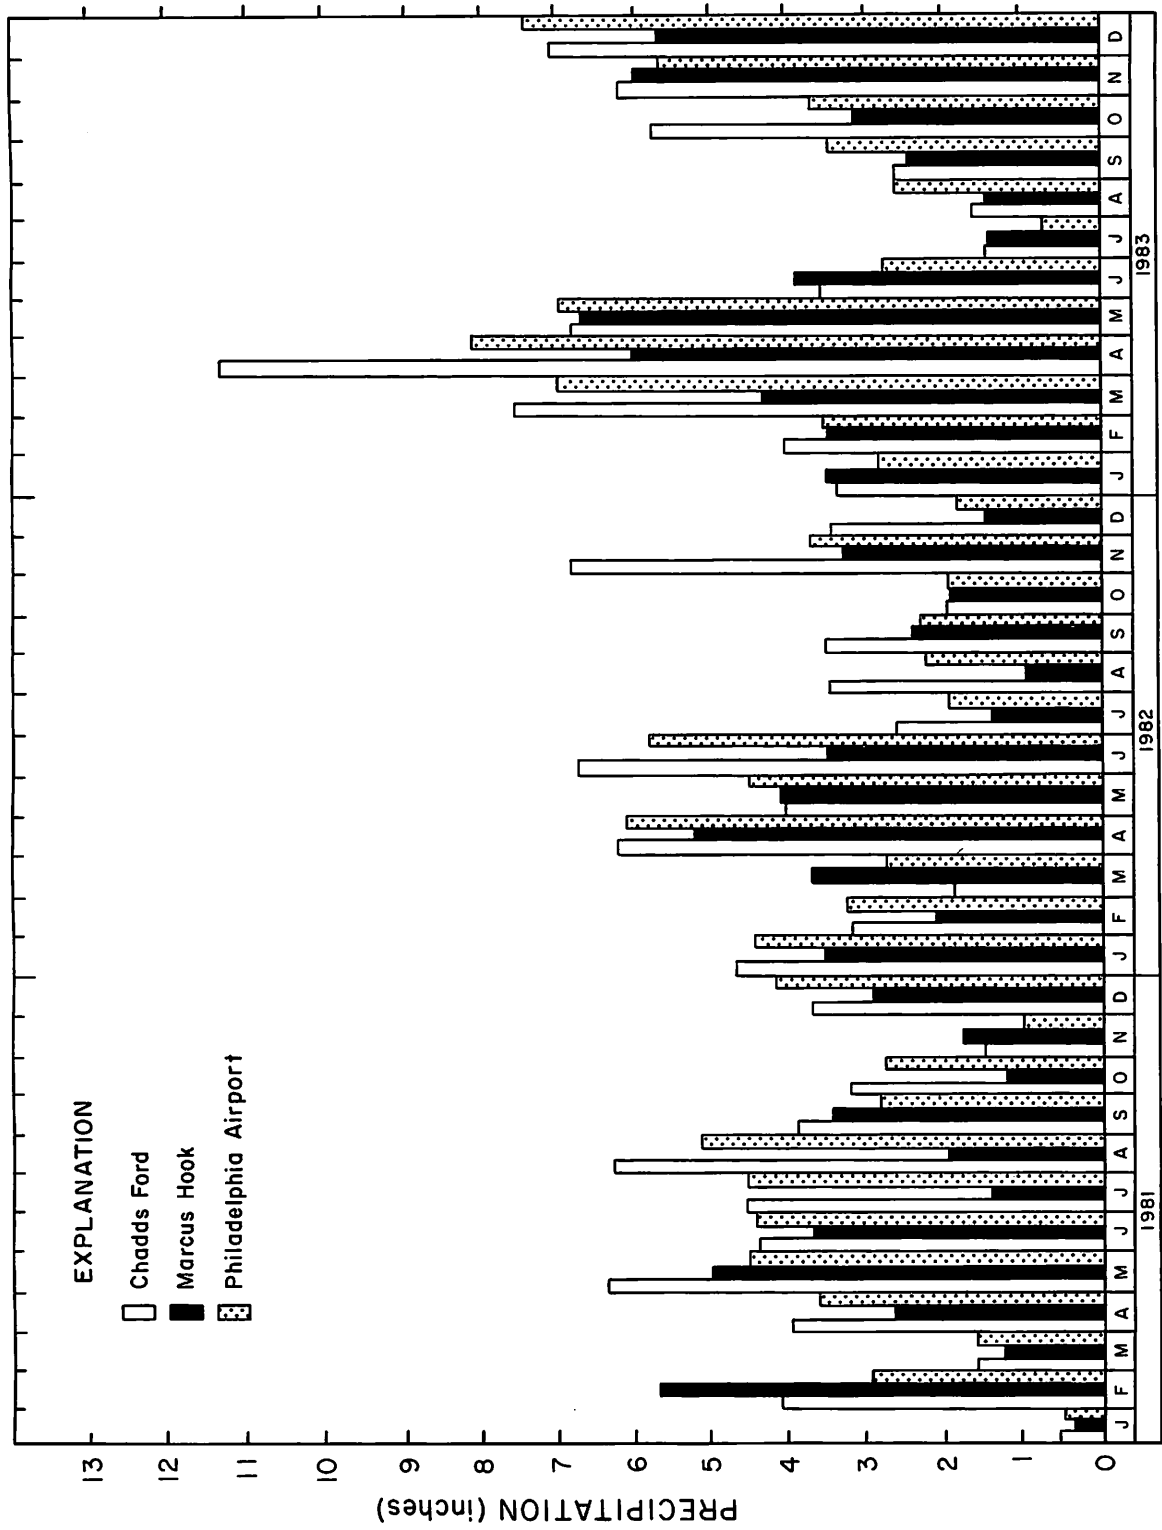

Figure 13. Monthly precipitation at Chadds Ford, Marcus Hook, and Philadelphia Airport for 1981-83.

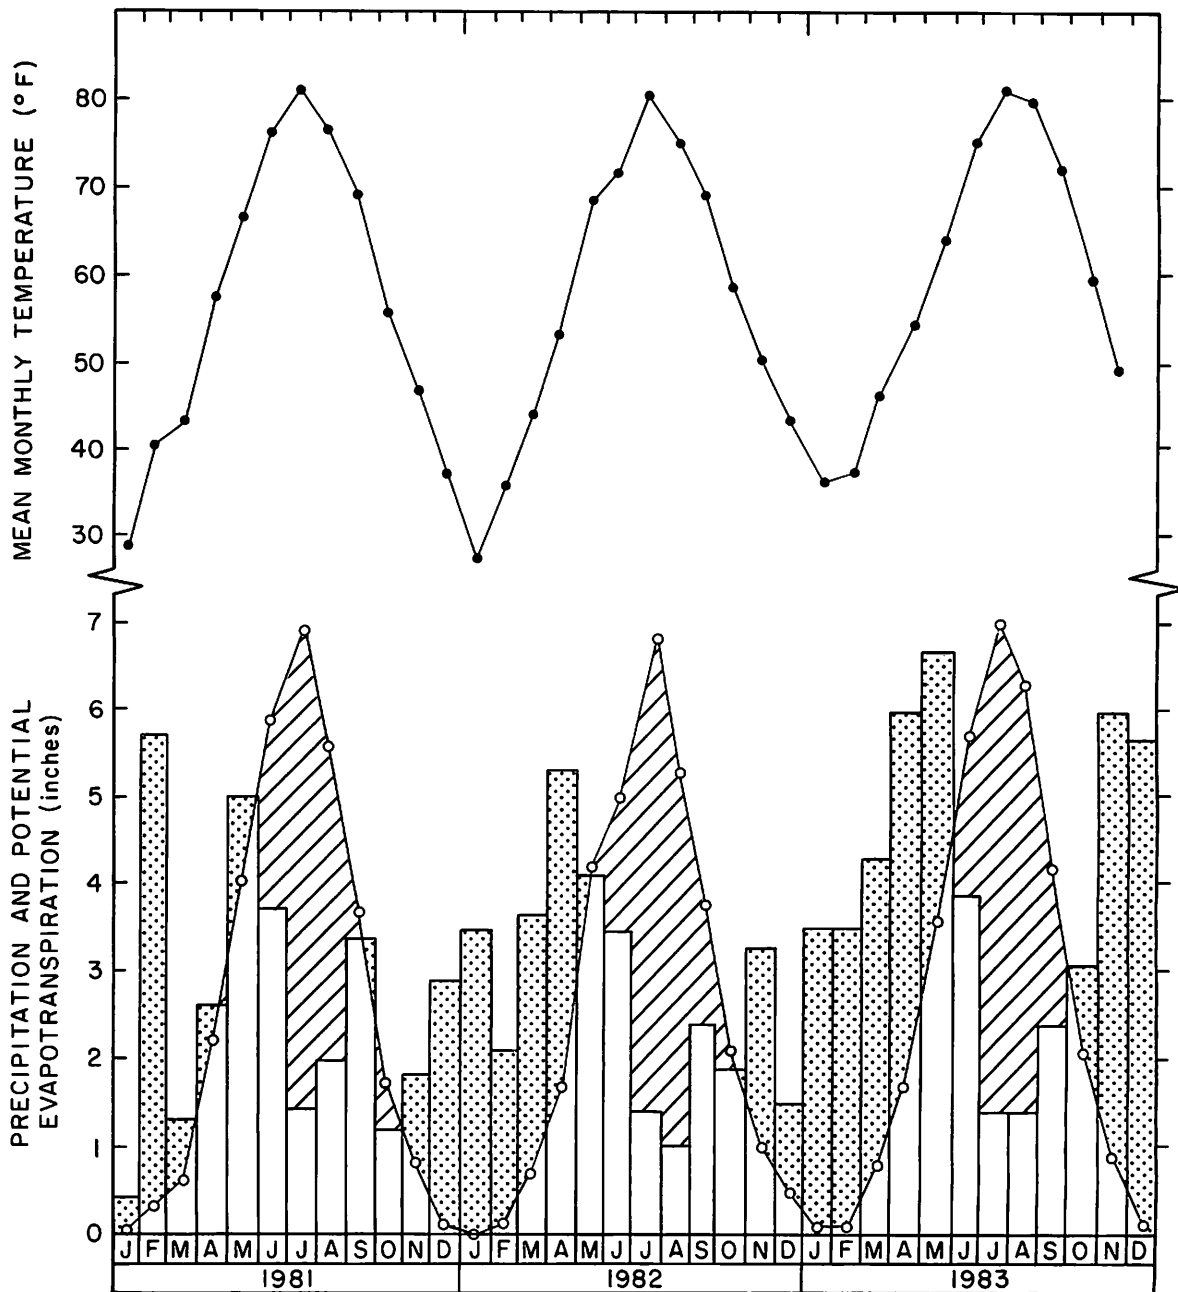

Figure 14. Mean monthly temperature, precipitation, and potential evapotranspiration at Marcus Hook, 1981–83. Dotted pattern, water surplus; diagonal pattern, water deficit.

comparable in the granodioritic and felsic gneiss, mafic gneiss, and ultramafite. The median depth for wells in anorthositic gneiss was not determined because of the small number of wells reported but is probably similar to that of the above rock types. The shallowest well depth in ultramafite is 80 feet, which is much deeper than the shallowest wells in the other rock units.

Figure 15 shows the cumulative frequency distributions of depths of drilled wells in the mafic gneiss,

granodioritic and felsic gneiss, and Wissahickon Formation. Deep wells are most prevalent in the Wissahickon Formation.

### Depths of Well Casings

The depths of well casings for the major water-bearing rock units are summarized in Table 13. Depth of well casing can be used to estimate the thickness of the weathered zone above solid bedrock, although

Table 11. *Relations of Well Yields, Depths to Water, and Depths of Well Casings to Topographic Position*

Topographic position	Well yield (gal/min)			Depth to water (feet)			Depth of well casing (feet)		
	Number of wells	Range	Median	Number of wells	Range	Median	Number of wells	Range	Median
Hilltop	43	0.50-65	10	39	5.87-250	34.5	38	12-85	38
Hillside	181	0-150	10	178	.74-179	27.0	172	14-486	40
Valley	62	3.0-300	30	52	.06-60.0	11.1	49	4-108	40

it is not a precise indicator because casing is commonly driven to a depth below the weathered zone.

The Wissahickon Formation, granodioritic and felsic gneiss, and mafic gneiss all have a median depth of casing of about 40 feet. The range of six casing depths for anorthositic gneiss is from 20 to 31 feet. These limited data suggest that the anorthositic gneiss is more resistant to weathering. The ultramafite has a median depth of casing of 62 feet. Thus, ultramafite is less resistant to weathering than the other consolidated rocks.

### Depths to Water

The depths to water for the major water-bearing rock units are summarized in Table 14. Depth to water is more dependent on well location than it is on rock type (see the section "Influence of Topography"). The median depth to water is highest for the granodioritic and felsic gneiss.

### Yields

Yield is usually considered to be the most important characteristic of a water-bearing rock unit.

Table 12. *Depths of Drilled Wells in the Major Water-Bearing Rock Units*

Geologic unit	Number of wells	Depth of wells (feet)	
		Range	Median
Trenton gravel	14	10-51	28
Anorthositic gneiss	6	49-360	— <sup>1</sup>
Granodioritic and felsic gneiss	147	43-500	142
Mafic gneiss	58	38-361	146
Ultramafite	9	80-340	117
Wissahickon Formation	132	43-675	187

<sup>1</sup>Dash indicates insufficient data.

The yields of wells for the major water-bearing rock units are summarized in Table 15. These figures were obtained without separation of wells by use. Sixty-six percent of the wells for which the use was reported are domestic wells, 20 percent are unused, and the remainder are distributed among other uses.

Wells in the Trenton gravel have the highest median yield at 50 gal/min; however, the limited thickness of these deposits limits the sustained withdrawal of large amounts of water. Wells in the Wissahickon Formation have the highest median yield for the crystalline water-bearing rock units at 20 gal/min. All of the crystalline water-bearing rock units have wells that yield less than 2 gal/min, which is considered the minimum necessary for a domestic supply. Wells in ultramafite have a median yield of 18 gal/min, or slightly less than that of the Wissahickon Formation, making ultramafite a fairly reliable water source. The maximum yield of nine wells in ultramafite was only 60 gal/min. Wells in the granodioritic and felsic gneiss and in the mafic gneiss have median yields of 6 gal/min and maximum yields of 100 and 150 gal/min, respectively.

Figure 16 shows the cumulative frequency distribution of the yields of wells in the mafic gneiss, granodioritic and felsic gneiss, and the Wissahickon Formation. Wells in the Wissahickon Formation have higher yields than those in the other rock units. About 10 percent of wells in this formation can be expected to yield 65 gal/min or more. Wells in the mafic gneiss yield less than wells in the other rock units. More than 20 percent of the wells in the mafic gneiss have yields of less than 2 gal/min.

Because well drilling is generally discontinued when a sufficient amount of water is encountered, yield cannot be directly correlated with depth. Table 16 gives the number of water-bearing zones per 100 feet of uncased borehole in specified depth intervals for each rock unit. Where the footage drilled per interval is large enough for comparison (greater than 400 feet) all of the units show a decreasing number of water-bearing zones penetrated with increasing depth.

Wissahickon Formation	127	1.0–300	20

<sup>1</sup>Dash indicates insufficient data.

Much of the water yielded by wells in the crystalline rocks is encountered within 300 feet of the land surface.

### Specific Capacities

Specific capacity is the ability of a well to produce a certain yield per foot of drawdown. Specific capacity is partially dependent on the degree of development of a well. Proper development can increase yield and specific capacity, providing a more consistent sustained yield over time.

Specific capacities for wells in the major water-bearing rock units are summarized in Table 17. Wells in the Trenton gravel deposits have the highest specific capacities because the Trenton gravel deposits have a much higher transmissivity than the crystalline rocks.

Wells in the Wissahickon Formation, granodioritic and felsic gneiss, and ultramafite all have a median specific capacity of about 0.2 (gal/min)/ft (gallons per minute per foot of drawdown). Wells in mafic gneiss have a median specific capacity of 0.08 (gal/min)/ft.

The frequency distributions of the specific capacities of wells in the mafic gneiss, granodioritic and felsic gneiss, and the Wissahickon Formation are shown in Figure 17. The specific capacities of wells in the mafic gneiss are consistently lower than those of wells in the other units.

### QUALITY

All data on groundwater quality that are available for Delaware County are presented in Tables 36 through 40. For wells for which two or more samples were collected, other tables in this report that include

water-quality data show only the most recent sample for data analysis. Table 18 gives the USEPA drinking-water-quality criteria for selected constituents.

### Field Determinations

Field determinations of hardness, pH, and specific conductance are summarized in Table 19. Hardness refers to the content of metallic ions, primarily  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , that react with sodium soaps to produce solids or scummy residue, and that react with anions when the water is evaporated in boilers to produce solid boiler scale (Camp, 1963). The calcium and magnesium ions associated with hardness also can cause corrosion. Water that has sufficient hardness to reduce the effectiveness of soap or cause boiler scale is undesirable. Determinations of the degree of hardness are based on the following generally accepted rating scale:

<i>Hardness range (mg/L of <math>\text{CaCO}_3</math>)</i>	<i>Description</i>
0–60	Soft
61–120	Moderately hard
121–180	Hard
More than 180	Very hard

Most of the water in Delaware County can be classified as soft to moderately hard, except for some water in the granodioritic and felsic gneiss that can be classified as hard and very hard. Hardness of water in the county ranges from 17 to 3,300 mg/L. The median hardness is similar for most crystalline-rock water-bearing units. One water sample from the Trenton gravel was determined in the laboratory to have a hardness of 140 mg/L. Although sample sizes for the Trenton gravel, ultramafite, and anorthositic gneiss were too small to derive medians, the ranges are comparable to those for the other units.

The pH of water is a measure of hydrogen-ion activity. Values greater than 7 indicate alkaline water, and values less than 7 indicate acidic water; a value of 7 is neutral. Acidic water tends to be corrosive and can dissolve trace metals more readily than can alkaline water. The pH of water for industrial purposes can be chemically altered to fit the needs of various processes. Water for domestic purposes can be treated adequately with water softening or neutralizing equipment.

Values of pH vary slightly in each rock unit. Water from the Wissahickon Formation has a pH range from 5.4 to 8.0 and a median pH of 6.4. Water from the mafic gneiss has the same median. Water from the granodioritic and felsic gneiss has the high-

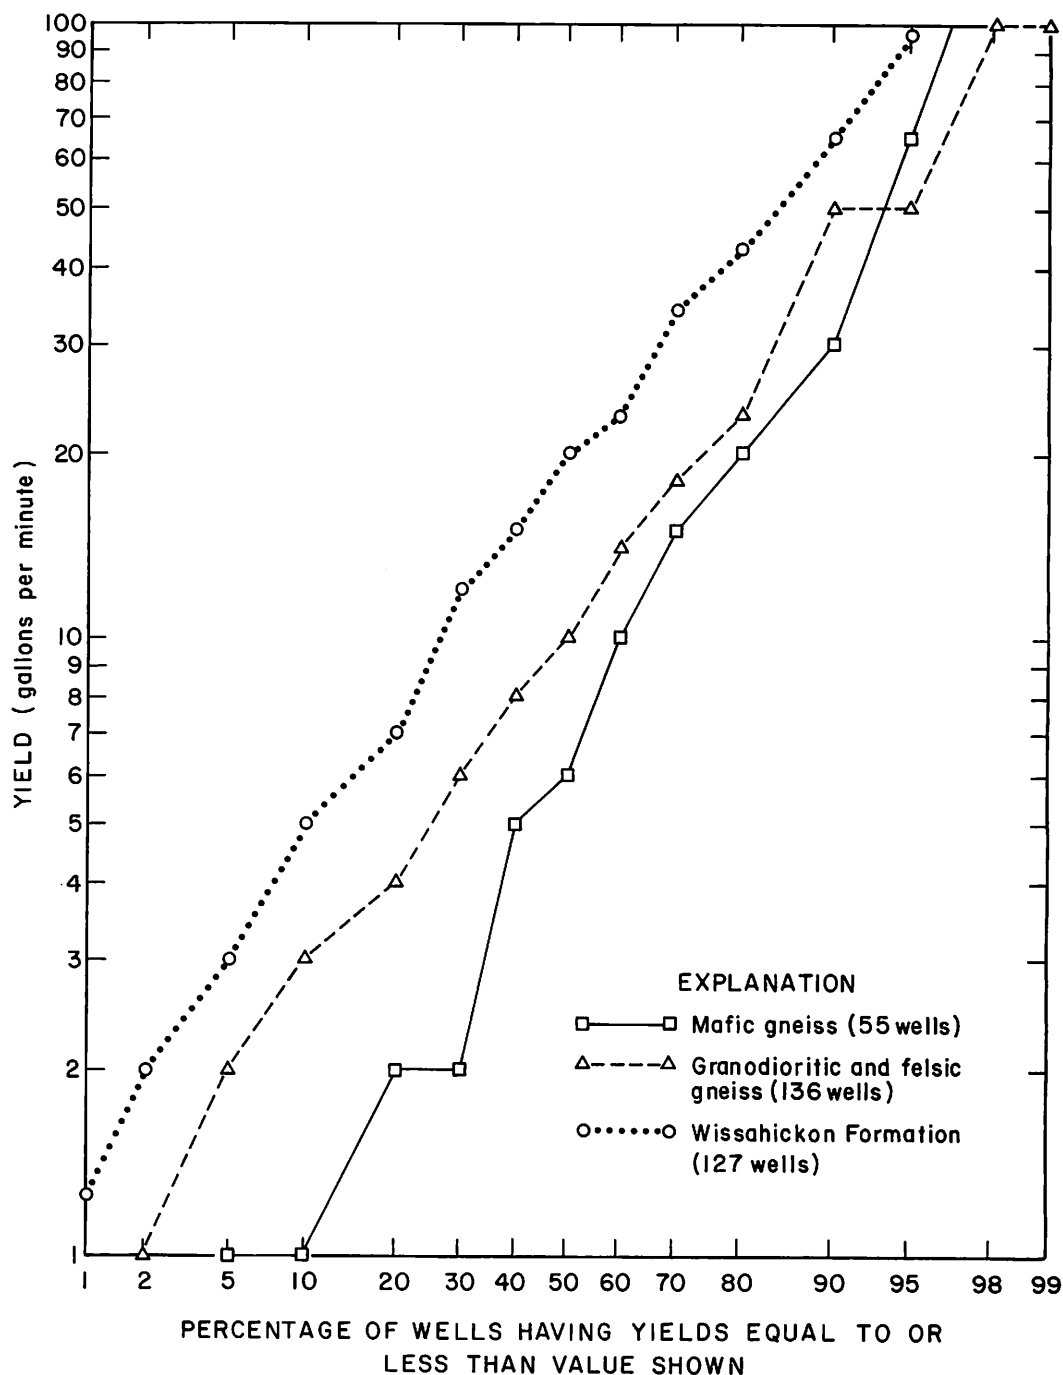

Figure 16. Cumulative frequency distributions of the reported yields of wells in the mafic gneiss, granodioritic and felsic gneiss, and Wissahickon Formation.

est median at 6.5. Four of five water samples from ultramafite are alkaline; however, this number of samples is insufficient to derive a median. One sample from the Trenton gravel tested in the laboratory has a pH of 7.6. The lowest measured pH is 5.2 from the mafic gneiss. Many of the samples tested were

below the USEPA recommended range of 6.5 to 8.5. Treatment is less expensive within this range, and the pH is easily adjusted.

Specific conductance is a measure of the ability of water to conduct an electrical current and depends on the amount and nature of the dissolved constituents

Table 16. Number of Water-Bearing Zones Reported Per 100 Feet of Uncased Borehole Drilled for the Major Crystalline Rock Units

Interval (feet)	Anorthositic gneiss (5 wells)			Granodioritic and felsic gneiss (118 wells)			Mafic gneiss (53 wells)			Ultramafite (8 wells)			Wissahickon Formation (88 wells)			All geologic units (272 wells)

Mafic gneiss	44	.002–6.0	.08
Ultramafite	8	.01–.6	.22
Wissahickon Formation	72	.004–2.9	.20

<sup>1</sup>Dashes indicate insufficient data.

in the water. Specific conductance of water from wells in the major water-bearing rock units ranges from 55  $\mu\text{mho/cm}$  (micromhos per centimeter at 25°C), recorded for water from the Wissahickon Formation, to 3,900  $\mu\text{mho/cm}$  for one sample of water from the granodioritic and felsic gneiss. The high value of specific conductance of this sample is caused by groundwater contamination. The Wissahickon Formation, granodioritic and felsic gneiss, and mafic gneiss all have similar median specific conductances. Those rock units in which the number of samples are too small to derive medians show similar ranges and values.

### Inorganic Constituents

The most recent laboratory analytical results for 42 wells for inorganic constituents are given in Table 20. Groundwater in Delaware County is generally of good quality, suitable for human consumption and most other uses. Nitrate concentrations for 37 water samples range from 0.07 to 7.2 mg/L, and the median is 2.6 mg/L (the USEPA maximum contaminant level [MCL] is 10 mg/L). Concentrations above this limit can be harmful to infants and possibly to adults if continually ingested. Sources of nitrates include fertilizers, decaying vegetation, animal wastes, and sewage.

Calcium concentrations in 38 water samples range from 4.2 to 140 mg/L; the median is 22 mg/L. The ultramafite, anorthositic gneiss, and mafic gneiss generally have the lowest concentrations of calcium. The granodioritic and felsic gneiss and the Wissahickon Formation have the widest ranges of calcium concentration, 11 to 140 mg/L and 12 to 130 mg/L, respectively. The median calcium concentration for the Wissahickon Formation is 32 mg/L.

Magnesium concentrations for 38 water samples range from 2.4 to 62 mg/L, and the median is 8.7

mg/L. Generally, water from ultramafite has the highest magnesium concentrations. The median concentrations in water from the other units are near 8.5 mg/L. Elevated concentrations of magnesium can corrode pipes and plumbing fixtures.

Sodium concentrations in 37 water samples range from 2.3 to 98 mg/L; the median is 9.3 mg/L. Water from the Wissahickon Formation has the highest median sodium concentration, 21 mg/L. Water from the other rock units generally has sodium concentrations of less than 15 mg/L.

Potassium concentrations were determined for 37 water samples; they range from 0.30 to 17 mg/L, and the median is 2.4 mg/L.

Chloride concentrations in 42 water samples range from below the detection limit to 1,800 mg/L, and the median is 23 mg/L. The USEPA MCL is 250 mg/L. Concentrations above this limit cause a noticeable salty taste, and elevated concentrations of chloride can corrode pipes and plumbing fixtures. Chlorides are not removed in conventional water treatment. Possible sources of high chloride concentrations are storage and runoff of highway deicing salts. The Wissahickon Formation has the highest concentrations of chloride, although the median is only 38 mg/L.

Concentrations of sulfate in 38 water samples range from 1.0 to 94 mg/L, and the median is 31 mg/L. These are all below the USEPA MCL of 500 mg/L. The highest concentration of sulfate, 94 mg/L, is in a sample from the Wissahickon Formation.

Total dissolved solids should not exceed the USEPA secondary maximum contaminant level (SMCL) of 500 mg/L because of adverse physiological effects, mineral taste, or corrosion of plumbing fixtures. Water in Delaware County generally is low in dissolved solids, ranging from 69 to a high of 1,600 mg/L, and having a median of 187 mg/L. Only two samples exceed a concentration of 400 mg/L. The USEPA has set no mandatory limit on total dissolved solids because standards have been set on the two most troublesome salts that contribute to its content, chlorides and sulfates.

Concentrations of iron for 38 water samples range from less than 3 to 120,000  $\mu\text{g/L}$ , and the median is 25  $\mu\text{g/L}$ . The USEPA SMCL is 300  $\mu\text{g/L}$ . The Wissahickon Formation has the highest median iron concentration, 180  $\mu\text{g/L}$ ; 6 out of 14 samples exceed the USEPA SMCL. All of the other rock units from which more than one sample was analyzed also have concentrations above the SMCL. Because it is easily precipitated, iron above this limit can stain ceramics, laundry, and pipes, and can also impart a disagreeable taste to drinking water.

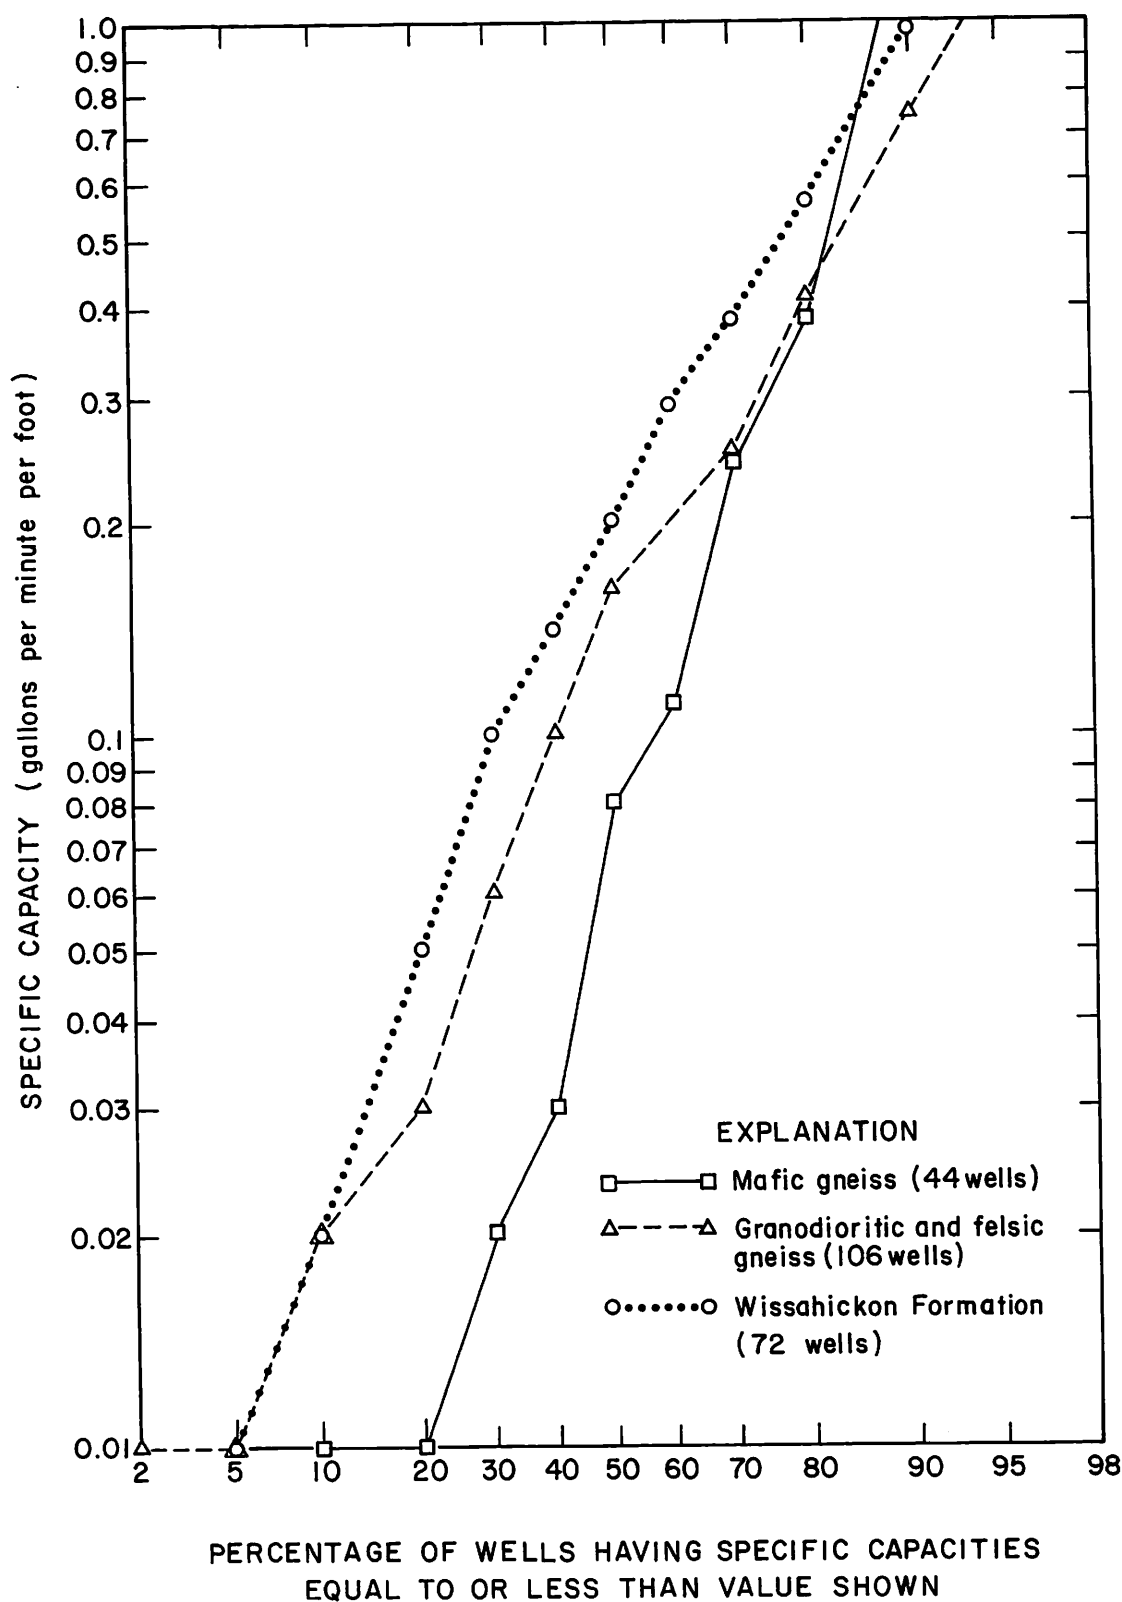

Figure 17. Cumulative frequency distributions of the specific capacities of wells in the mafic gneiss, granodioritic and felsic gneiss, and Wissahickon Formation.

Table 18. *Maximum Concentrations for Selected Dissolved Constituents Established for Drinking Water*

(From U.S. Environmental Protection Agency, 1996)

Constituent	Criterion
Chloride	250 mg/L
Iron	300 µg/L
Lead	15 µg/L
Manganese	50 µg/L
Nitrate, dissolved as nitrogen	10 mg/L
pH (range)	6.5–8.5 units
Sulfate	500 mg/L

Concentrations of lead in 31 water samples range from less than 1 to 14 µg/L; the median is 5 µg/L. The USEPA action level is 15 µg/L. Lead is toxic and tends to accumulate in the tissues of humans and other mammals. Lead amounts in all samples tested are below the action level.

Concentrations of manganese in 33 samples range from less than 1 to 13,000 µg/L, and the median is 11 µg/L. The USEPA SMCL is 50 µg/L. Water in all rock units contains acceptable levels of manganese except the Wissahickon Formation, in which 9 of 13 samples have concentrations above the USEPA limit. Manganese, which is commonly associated with iron, can cause a bitter taste as well as contribute to staining of laundry and fixtures.

Concentrations of nickel in 31 samples range from less than 1 to 13 µg/L, and have a median of 2 µg/L.

### Phenols and Organic Compounds

Approximately 17 water samples were analyzed for phenols and volatile organic compounds. Table 21 lists those analyses in which detectable concentrations of phenols or volatile organic compounds were observed. The USEPA has established a health advisory for children of 6 µg/L for phenols (total) in water. Water samples from wells De-844 and De-867 contain 2 µg/L. Phenolic compounds are used in industrial and medical applications as chemical reagents and disinfectants. They are toxic to humans through ingestion or skin absorption (Windholz and others, 1976, p. 941). All of these detected substances are synthetic and represent the contamination of groundwater by man's activities. Although statistical conclusions cannot be drawn from this sample size, groundwater contamination by organic compounds has occurred in Delaware County.

### Site-Specific Contamination

Improper storage and disposal of chemicals have resulted in contamination of groundwater in Delaware County. In their study for the USEPA, Pease and Lewis (1982) described a property that was formerly the site of a company that stripped and recycled tires and other rubber products. The site is in the city of Chester and is along the Delaware River adjacent to the Commodore Barry Bridge. It became the eventual dump site for approximately 2,500 drums and five large tanker containers of toxic chemicals, mainly cyanides, flammable organic compounds, organic and nonorganic aqueous solutions, solids, and sludges.

The site is underlain by the Trenton gravel, which is between 15 and 25 feet thick locally and overlies the Wissahickon Formation. Pease and Lewis (1982) determined that the site is in an area of groundwater discharge to the Delaware River; the hydraulic gradient is low, and some local recharge occurs. A major fire, acid gas fumes, and contamination of air, soil, and groundwater have resulted from the improper storage and disposal of the chemicals. According to the study, soil and groundwater contaminants consist of numerous organic and metal compounds. Some of the latter were determined to have migrated from off-site locations, indicating that this may not be the only contaminated site in the area. The flow of contaminated groundwater to the Delaware River was estimated to be 2,000 gal/day, which, although important, is insignificant compared to the flow of the river. No regional hydrogeologic connections are known to exist.

In a study for the USEPA, Dennis (1984) stated that, from 1947 to 1963, a 2-acre property in Haverford Township was used as the site of a wood-preserving facility. Pentachlorophenol (PCP), dissolved in an oil base, was used for the wood-preserving processes. A shallow injection well was used to dispose of the oil and PCP mixture. Also, significant quantities of preservative probably entered the soil and groundwater from routine handling and spills.

Naylors Run, a tributary to Cobbs Creek, is located in the vicinity of the wood-preserving facility. The area is underlain by the Wissahickon Formation. Oil and PCP contamination of the groundwater occurred over 4.5 acres. The contamination reached Naylors Run through infiltration and flow in a storm sewer discharging to the stream. Aquatic life was absent within 1 mile downstream of the site, and was stressed farther downstream where the contaminants were diluted and somewhat dispersed. Initial treatment consisted of pumping and treating contaminated groundwater from three recovery wells. Although

Table 19. Hardness, pH, and Specific Conductance of Water From Wells in the Major Water-Bearing Rock Units

some oil and PCP were recovered, a large quantity of oil- and PCP-contaminated groundwater remains in the vicinity of the site. Oil and PCP continues to discharge, but most of it is collected before it enters Naylor Run.

## MAJOR WATER-BEARING FORMATIONS

### Undifferentiated Unconsolidated Deposits

#### Description

Unconsolidated deposits overlie approximately 20 percent of the county. They are present mostly in the eastern part bordering the Delaware River. The high-elevation terrace deposits of the Bridgeton Formation (represented on Plate 1 as Tb) and the Bryn Mawr Formation (Tbm) are unimportant as water-bearing formations, except that they provide additional recharge and storage for the crystalline rocks beneath them. The remainder of the unconsolidated deposits consists of the informally named Trenton gravel (Qt). In this report, unless otherwise specified, data for wells in unconsolidated deposits refer exclusively to the Trenton gravel.

The Trenton gravel is discontinuous in extent and variable in depth. It consists of gravelly sand interstratified with semiconsolidated sand (limonite-cemented) and clay-silt beds. The sediments are poorly sorted, and the wide range in grain size causes the hydrologic properties to vary considerably. The Trenton gravel is commonly gray or pale reddish brown in color. It is present in the lowlands along the Delaware River at elevations of 50 feet or less. It ranges

up to 50 feet in thickness but generally is less than 20 feet thick.

The Trenton gravel generally overlies the Wissahickon Formation, except in the extreme northeast corner of the Delaware County part of the Atlantic Coastal Plain, where it overlies the Cretaceous Potomac-Raritan-Magothy aquifer system. In this small area, the Trenton gravel and the Cretaceous sediments probably act as a single aquifer. Otherwise, throughout the county, the Trenton gravel is too discontinuous to act as a single regional aquifer.

#### Water-Bearing Characteristics

The Trenton gravel is rarely tapped by wells in Delaware County. Nevertheless, it does yield moderate to large supplies of water to wells in some areas, especially where the wells are located near sources of recharge such as undeveloped flat-lying areas. In many areas, the deposits probably are too thin to yield much water to wells over a sustained period, but they do provide temporary storage of water that recharges the underlying units.

Reported data for wells in the Trenton gravel are summarized in Table 22. The depths of wells in the Trenton gravel range from 10 to 51 feet below land surface; the median is 28 feet. Although the statistical sample size is small, the average thickness of the Trenton gravel is probably about 20 feet.

The depths to water in wells in the Trenton gravel range from 0.1 to 15 feet below land surface. This shallow depth to water is related to the proximity of the Trenton gravel to the Delaware River.

The yields of wells in the Trenton gravel range from 8.0 to 200 gal/min; the median is 50 gal/min. Although this is the highest median yield of any of the water-bearing rock units in the county, the gravel should not be considered a major water source because it is generally too thin and discontinuous in most areas. Specific capacities for 3 wells range from 1.3 to 2.6 (gal/min)/ft.

Table 22. Summary of Hydrologic Characteristics for Wells in the Trenton Gravel

Hydrologic characteristic	Number of wells	Range	Median
Depth of well (feet)	14	10-51	28
Depth to water (feet)	7	.1-15	— <sup>1</sup>
Yield (gal/min)	9	8.0-200	50
Specific capacity [(gal/min)/ft]	3	1.3-2.6	—

<sup>1</sup>Dashes indicate insufficient data.

### Quality of Water

One water sample from well De-28 in the Trenton gravel was analyzed in the laboratory. The results of this analysis are reported in Tables 19 and 20. General conclusions cannot be drawn from one sample. The hardness of the sample is 140 mg/L; the pH, 7.6; and the specific conductance, 362  $\mu\text{mho/cm}$ . The nitrate concentration is 4.7 mg/L; the calcium concentration, 33 mg/L; and the magnesium concentration, 15 mg/L. Of the common salts, the chloride concentration is below the detection limit, and the sulfate concentration is 79 mg/L. Iron was found at a concentration of 340  $\mu\text{g/L}$ , and manganese concentration is below the detection limit. None of these constituents exceed the USEPA criteria for drinking water.

## Anorthositic Gneiss

### Description

Anorthositic gneiss (represented as wan on Plate 1) is a hard, medium- to coarse-grained crystalline rock that commonly forms hills and ridges. Anorthositic gneiss is present as metamorphosed intrusive bodies and is thought to be of early Paleozoic or Proterozoic Z age. The chief minerals are the feldspars calcic plagioclase and labradorite. It is typically light to dark bluish gray and has spheroidal weathering at the surface. Fresh exposures are pinkish gray and lack the secondary development of zoisite, which replaces the feldspars. Anorthositic gneiss is present in the extreme southern tip of Delaware County. Approximately 2 percent of the county is underlain by anorthositic gneiss.

### Water-Bearing Characteristics

Hydrologic data for anorthositic gneiss are available for only six wells. Water is present in secondary fractures and openings. Hydrologic characteristics of wells in anorthositic gneiss are given in Table 23. The depths of wells range from 49 to 360 feet below land surface; this is comparable to ranges for the other major water-bearing units in the county. Anorthositic gneiss is a very resistant rock; therefore, the depth of the weathered zone generally is less than that of other rock units. The depths of well casings range from 20 to 31 feet below land surface. The depths to water range from 7 to 35 feet below land surface.

The yields of wells completed in anorthositic gneiss range from 1.0 to 35 gal/min, and yields of most wells are insufficient for anything but single-family domestic supplies. Major water-bearing zones appear to be shallow because no wells deeper than

Table 23. Summary of Hydrologic Characteristics for Wells in Anorthositic Gneiss

Hydrologic characteristic	Number of wells	Range
Depth of well (feet)	6	49–360
Depth of well casing (feet)	6	20–31
Depth to water (feet)	6	7.1–35
Yield (gal/min)	6	1.0–35
Specific capacity [(gal/min)/ft]	5	.01–.50

200 feet yield more than 6.0 gal/min. Topographic location may not influence yield in this rock unit to the degree it does in other major water-bearing rock units in Delaware County. The specific capacities of wells in anorthositic gneiss range from 0.01 to 0.50 (gal/min)/ft. This small range is probably the result of the small number of wells studied.

### Quality of Water

Field determinations for hardness, pH, and specific conductance were made for water from three wells in anorthositic gneiss. The results are given in Table 24. A water sample from well De-200 was tested in the laboratory, and the analytical results are given in Table 20.

## Granodioritic and Felsic Gneiss

### Description

The granodioritic and felsic gneiss includes foliated metamorphic rocks containing predominantly

Table 24. Summary of Water-Quality Data for Wells in Anorthositic Gneiss

(Quantities are in milligrams per liter unless otherwise indicated)

Parameter	Number of samples	Range
Hardness (as calcium carbonate)	3	68–170
pH (units)	3	6.3–7.6
Specific conductance ( $\mu\text{mho/cm}$ )	3	160–450
Nitrate (as nitrogen)	1	5.9
Calcium	1	14
Magnesium	1	7.4
Sodium	1	8.6
Potassium	1	1.5
Chloride	1	12
Sulfate	1	4.6
Total dissolved solids	1	140
Iron ( $\mu\text{g/L}$ )	1	210

light minerals such as quartz and feldspar. The rocks are generally medium grained, and some of the felsic gneiss units contain pyroxene and/or hornblende. The felsic gneiss (Ybfa and Ybfg on Plate 1) is of Proterozoic Y age, whereas the granodioritic gneiss (gr) is of early Paleozoic or Proterozoic Z age. The water-bearing properties of the felsic gneiss and the granodioritic gneiss are similar, and, in this report, they are considered together. Water is present in secondary openings in the rock. Approximately 28 percent of the county is underlain by granodioritic and felsic gneiss.

### Water-Bearing Characteristics

The hydrologic characteristics of wells in the granodioritic and felsic gneiss are summarized in Table 25. In Table 26, the cumulative frequency distributions of depths of wells, depths of well casings, depths to water, yields, and specific capacities are listed.

The reported depths of wells in the granodioritic and felsic gneiss range from 43 to 500 feet below land surface; the median is 142 feet. This is the second-widest range of well depths in the county. The median well depth is similar to that of the mafic gneiss. Seventy-five percent of wells completed in granodioritic and felsic gneiss are at least 100 feet deep. Only 25 percent are 220 feet or deeper.

The reported depths of casings of wells in granodioritic and felsic gneiss range from 6 to 108 feet below land surface; the median is 40 feet. These are similar to the depths of casings for mafic gneiss and the Wissahickon Formation. Only 10 percent of wells completed in granodioritic and felsic gneiss have depths of well casings less than 21 feet below land

Table 25. *Summary of Hydrologic Characteristics for Wells in the Granodioritic and Felsic Gneiss*

Hydrologic characteristic	Number of wells	Range	Median
Depth of well (feet)	147	43–500	142
Depth of well casing (feet)	129	6–108	40
Depth to water (feet)	134	1–250	29
Yield (gal/min)	136	0–100	10
Specific capacity [(gal/min)/ft]	106	.002–14	.16

surface; only 25 percent of the wells have well-casing depths of 50 feet or greater.

The reported depths to water in wells in granodioritic and felsic gneiss range from 1 to 250 feet below land surface; the median is 29 feet. This is the highest median for depths to water of all the water-bearing rock units in the county. Ninety percent of the wells in granodioritic and felsic gneiss have depths to water of at least 10 feet. Twenty-five percent of the wells have depths to water of 40 feet or more.

The reported yields of wells in the granodioritic and felsic gneiss range from 0 to 100 gal/min, and the median is 10 gal/min. This median is comparable to that of the mafic gneiss. Most water-bearing zones encountered are less than 250 feet below land surface. High yields should not be expected because the maximum reported yield is only 100 gal/min. Only 25 percent of wells in this formation have yields that equal or exceed 20 gal/min, and 25 percent of the wells have yields of less than 5 gal/min.

Table 26. *Cumulative Frequency Distributions of Reported Well Depths, Depths of Well Casings, Depths to Water, Yields, and Specific Capacities for Wells in the Granodioritic and Felsic Gneiss*

Hydrologic characteristic	Number of wells	90 percent <sup>1</sup>	75 percent <sup>1</sup>	50 percent <sup>1</sup>	25 percent <sup>1</sup>	10 percent <sup>1</sup>
Depth of well (feet)	147	75	100	142	220	300
Depth of well casing (feet)	129	21	28	40	50	62
Depth to water (feet)	134	10	16	29	40	56
Yield (gal/min)	136	3	5	10	20	50
Specific capacity [(gal/min)/ft]	106	.02	.05	.16	.36	.74

<sup>1</sup>Percentage of wells in which indicated value is equaled or exceeded.

The reported specific capacities of wells in the granodioritic and felsic gneiss range from 0.002 to 14 (gal/min)/ft; the median is 0.16 (gal/min)/ft. This is comparable to specific capacities for the other water-bearing units in the county. Only 10 percent of wells in this unit have a specific capacity of 0.74 (gal/min)/ft or more.

The probability of obtaining higher yields is increased by locating wells in valleys or draws. Wells can be expected to yield 10 gal/min and can yield up to 40 gal/min if properly located and developed.

### Quality of Water

Water-quality data for wells in the granodioritic and felsic gneiss are summarized in Table 27. The hardness of water samples ranges from 32 to 3,300 mg/L; the median is 86 mg/L. The median is slightly higher than that of the other units. Only three samples have hardnesses greater than 300 mg/L. Most water in the granodioritic and felsic gneiss is soft to moderately hard.

The pH of water from the granodioritic and felsic gneiss ranges from 5.4 to 7.9, and the median is 6.5. The observed values of pH for the granodioritic and felsic gneiss are evenly distributed about the median.

The specific conductance of water ranges from 60 to 3,900  $\mu$ mho/cm, and the median is 210  $\mu$ mho/cm. Only three samples exceed 500  $\mu$ mho/cm, most likely because of site-specific contamination.

Table 27. *Summary of Water-Quality Data for Wells in the Granodioritic and Felsic Gneiss*

(Quantities are in milligrams per liter unless otherwise indicated)

Parameter	Number of samples	Range	Median
Hardness (as calcium carbonate)	66	32–3,300	86
pH (units)	67	5.4–7.9	6.5
Specific conductance ( $\mu$ mho/cm)	68	60–3,900	210
Nitrate (as nitrogen)	12	<.10–6.3	2.6
Calcium	13	11–140	23
Magnesium	13	3.3–41	9.0
Sodium	13	4.5–15	9.0
Potassium	13	1.3–17	2.3
Chloride	17	5.2–1,800	20
Sulfate	13	4.3–46	31
Total dissolved solids	13	85–929	190
Iron ( $\mu$ g/L)	13	<3–4,100	8
Lead ( $\mu$ g/L)	12	2–13	5
Manganese ( $\mu$ g/L)	12	<1–75	4
Nickel ( $\mu$ g/L)	12	1–7	3

Chloride concentrations range from 5.2 to 1,800 mg/L; the median is 20 mg/L. Only two samples tested have concentrations of chloride greater than the USEPA MCL of 250 mg/L. These concentrations are probably caused by site-specific contamination.

The water from 13 wells in the granodioritic and felsic gneiss was analyzed for iron. Iron ranges from less than 3 to 4,100  $\mu$ g/L; the median is 8  $\mu$ g/L. Water from two wells has concentrations above the USEPA SMCL of 300  $\mu$ g/L.

### Mafic Gneiss

#### Description

The mafic gneiss consists of dark medium-grained metamorphic rocks of early Paleozoic and/or Proterozoic Z age (wbma, wma, pma, and wmg on Plate 1) and Proterozoic Y age (Ybma and Ybmg). They are generally of gneissic texture and are either hornblende- or pyroxene-bearing. They are generally gray but can also be green, brown, or black. This lithology underlies approximately 11 percent of the county. In this report, all of the mafic gneisses are considered as one water-bearing unit.

#### Water-Bearing Characteristics

The hydrologic characteristics for wells in the mafic gneiss are summarized in Table 28. In Table 29, the cumulative frequency distributions of depths of wells, depths of well casings, depths to water, yields, and specific capacities are listed.

The reported depths of wells in mafic gneiss range from 38 to 361 feet below land surface, and the median is 146 feet. This is similar to the depths of wells in granodioritic and felsic gneiss. Ninety percent of the wells in the mafic gneiss are at least 58 feet deep. Seventy-five percent of the wells are less than 238 feet deep.

The reported depths of casings of wells in the mafic gneiss range from 16 to 105 feet below land

Table 28. *Summary of Hydrologic Characteristics for Wells in the Mafic Gneiss*

Hydrologic characteristic	Number of wells	Range	Median
Depth of well (feet)	58	38–361	146
Depth of well casing (feet)	54	16–105	40
Depth to water (feet)	53	2–180	25
Yield (gal/min)	55	.5–150	6
Specific capacity [(gal/min)/ft]	44	.002–6.0	.08

Table 29. *Cumulative Frequency Distributions of Reported Well Depths, Depths of Well Casings, Depths to Water, Yields, and Specific Capacities for Wells in the Mafic Gneiss*

Hydrologic characteristic	Number of wells	90 percent <sup>1</sup>	75 percent <sup>1</sup>	50 percent <sup>1</sup>	25 percent <sup>1</sup>	10 percent <sup>1</sup>
Depth of well (feet)	58	58	100	146	238	300
Depth of well casing (feet)	54	21	30	40	61	74
Depth to water (feet)	53	9	15	25	35	48
Yield (gal/min)	55	1	2	6	16	30
Specific capacity [(gal/min)/ft]	44	.01	.01	.08	.26	1.2

<sup>1</sup>Percentage of wells in which indicated value is equaled or exceeded.

surface, and the median is 40 feet. Seventy-five percent of the well casing depths are 30 feet or more below land surface; only 10 percent are 74 feet or deeper.

The reported depths to water for wells in the mafic gneiss range from 2 to 180 feet below land surface; the median is 25 feet. This is the second-greatest median depth to water for all of the water-bearing rock units in the county. In 90 percent of the wells, the depth to water is 9 feet or more below land surface. Depth to water is 48 feet or more for only 10 percent of the wells reported.

The reported yields of wells in the mafic gneiss range from 0.5 to 150 gal/min; the median is 6 gal/min. Only 10 percent of the reported well yields are 30 gal/min or greater. Twenty-five percent of the reported yields are less than 2 gal/min.

The specific capacities of wells in the mafic gneiss range from 0.002 to 6.0 (gal/min)/ft, and the median is 0.08 (gal/min)/ft. This is the lowest median specific capacity for any of the rock units in the county, although the medians for all other units were 0.2 (gal/min)/ft. Only 10 percent of the reported specific capacities for wells in the mafic gneiss are 1.2 (gal/min)/ft or greater.

Generally, the chances of finding water below 300 feet are low, but are better than for the other crystalline rocks (Table 16). The probability of obtaining a higher yield is increased by locating wells in valleys or draws. Wells can be expected to yield 10 gal/min and can yield up to 30 gal/min if properly located and developed.

### Quality of Water

Water-quality data for wells in the mafic gneiss are summarized in Table 30. The hardness ranges

from 17 to 240 mg/L; the median is 77 mg/L. Most of the samples are classified as soft to moderately hard. Only three samples are classified as hard and two samples are very hard.

The pH of water from the mafic gneiss ranges from 5.2 to 7.4, and the median is 6.4. The specific conductance ranges from 60 to 600  $\mu$ mho/cm, and the median is 185  $\mu$ mho/cm. All of these values are comparable to the other units in the county.

The water from six wells in the mafic gneiss was analyzed for trace metals. Iron concentrations range from 12 to 4,000  $\mu$ g/L; the median is 90  $\mu$ g/L. Water from two wells exceeds the USEPA SMCL for iron.

Table 30. *Summary of Water-Quality Data for Wells in the Mafic Gneiss*

(Quantities are in milligrams per liter unless otherwise indicated)

Parameter	Number of samples	Range	Median
Hardness (as calcium carbonate)	30	17–240	77
pH (units)	29	5.2–7.4	6.4
Specific conductance ( $\mu$ mho/cm)	30	60–600	185
Nitrate (as nitrogen)	6	.07–3.6	2.8
Calcium	6	8.0–36	16
Magnesium	6	6.0–12	7.7
Sodium	6	6.4–37	9.8
Potassium	6	.8–2.8	1.8
Chloride	6	9.6–100	24
Sulfate	6	1.0–40	25
Total dissolved solids	6	69–346	130
Iron ( $\mu$ g/L)	6	12–4,000	90

Manganese ( $\mu$ g/L)	5	1–95	16
Nickel ( $\mu$ g/L)	5	<1–3	2

## Ultramafite

### Description

Ultramafite is a magnesium-rich rock derived from pyroxenite and peridotite. The pyroxenite and peridotite were probably intruded into the Wissahickon Formation during the early Paleozoic or Proterozoic Z, then hydrothermally altered to ultramafite. The ultramafite is composed primarily of serpentine, which is a group of hydrous magnesium silicate minerals. It ranges in color from buff to emerald green, and can be various shades of gray or bluish gray. It generally has a greenish hue and commonly has an oily appearance.

The ultramafite is well jointed and fractured. The joints and fractures, which commonly are numerous and may extend to a considerable depth, may hold considerable volumes of water. These secondary openings are responsible for water storage and transport. Although the ultramafite is well jointed and fractured and is a soft building material, it is rather inert and resistant to ordinary chemical weathering. Therefore, it tends to form low hills and ridges. Areas underlain by ultramafite are characterized by thin, low-fertility soils. Typically, springs and areas of high-yielding wells may be found in valleys that bisect the hills and ridges and at contacts with other rock units.

Two large areas of ultramafite (wum on Plate 1) are present in central Delaware County near Lima and Larchmont. Numerous smaller exposures are present throughout the county, but are not significant as aquifers. Approximately 4 percent of the county is underlain by ultramafite.

### Water-Bearing Characteristics

Well data for ultramafite are sparse. The ranges of well depths, depths of well casings, depths to water, yields, and specific capacities for nine wells completed in ultramafite are presented in Table 31. The range of well depths is narrow compared to the other major water-bearing rock units. Few shallow wells have been drilled in ultramafite. This may be the result of fracturing at depth, as suggested by the high values of depths of casings, which range from 43 to 90 feet below land surface. The median depth of casing, 62 feet, is deeper than that of the other rock units in the county and is probably indicative of the fractured nature of the rock rather than the depth of weathering.

The depths to water in ultramafite range from 5.0 to 40 feet below land surface; the median is 20.0 feet. This is shallow compared to the other rock units

Table 31. Summary of Hydrologic Characteristics for Wells in the Ultramafite

Hydrologic characteristic	Number of wells	Range	Median
Depth of well (feet)	9	80–340	117
Depth of well casing (feet)	8	43–90	62
Depth to water (feet)	8	5.0–40	20
Yield (gal/min)	9	2.0–60	18
Specific capacity [(gal/min)/ft]	8	.01–.6	.22

in the county, especially considering that seven of the eight wells in the data set were drilled on hillsides or hilltops.

The yields of wells in ultramafite range from 2.0 to 60 gal/min; the median is 18 gal/min. This is the second-highest median yield for all of the water-bearing units in the county. Most water-bearing zones encountered are less than 250 feet below land surface.

The specific capacities of wells in ultramafite range from 0.01 to 0.6 (gal/min)/ft, and the median is 0.22 (gal/min)/ft. This is comparable to the other major water-bearing rock units.

Wells should yield about 18 gal/min if properly located and developed, and specific capacities of about 0.2 (gal/min)/ft can be expected.

### Quality of Water

Field determinations of hardness, pH, and specific conductance were made on five water samples from wells in ultramafite. A summary of field and laboratory analytical results of well water from ultramafite are given in Table 32. The hardness ranges from 68 to 190 mg/L; most of the water samples are classified as moderately hard. The pH ranges from 6.1 to 7.6; most of the samples are alkaline. The specific conductance ranges from 150 to 360  $\mu$ mho/cm.

Magnesium concentrations range from 2.4 to 18 mg/L; these are the highest in the county and are caused by the high magnesium content of the rock.

Iron concentrations of three samples are 4, 5, and 5,400  $\mu$ g/L; this last concentration exceeds the USEPA SMCL of 300  $\mu$ g/L.

## Wissahickon Formation

### Description

The Wissahickon Formation consists of dark amphibolite, light augen gneiss, and quartz- and feldspar-rich and schistose members. It is the most prevalent rock unit at the surface in Delaware County. The Wissahickon is represented on Plate 1 by the symbols wb

Table 32. *Summary of Water-Quality Data for Wells in the Ultramafite*

(Quantities are in milligrams per liter unless otherwise indicated)

Parameter	Number of samples	Range/value
Hardness (as calcium carbonate)	5	68–190
pH (units)	5	6.1–7.6
Specific conductance (µmho/cm)	5	150–360
Nitrate (as nitrogen)	3	1.4–7.2
Calcium	3	4.2–8.9
Magnesium	3	2.4–18
Sodium	3	2.3–3.7
Potassium	3	.3–1.8
Chloride	3	8.1–11
Sulfate	3	3.2–26
Total dissolved solids	3	111–182
Iron (µg/L)	3	4–5,400
Lead (µg/L)	2	2–7
Manganese (µg/L)	2	<1–2
Nickel (µg/L)	2	2

and wp. It comprises approximately 34 percent of the exposed formations in Delaware County and underlies most of the unconsolidated deposits.

The Wissahickon Formation was originally sediment of variable thickness and composition. The original sediments have been completely recrystallized by metamorphism. The formation is highly variable in composition and degree of metamorphism. Its thickness is estimated to be 5,000 to 8,000 feet.

#### *Water-Bearing Characteristics*

The Wissahickon Formation is the most productive of the water-bearing rock units in Delaware County.

Table 33. *Summary of Hydrologic Characteristics for Drilled Wells in the Wissahickon Formation*

Hydrologic characteristic	Number of wells	Range	Median
Depth of well (feet)	132	43–675	187
Depth of well casing (feet)	114	4–127	40
Depth to water (feet)	112	1–85	20
Yield (gal/min)	127	1–300	20
Specific capacity [(gal/min)/ft]	72	.004–2.9	.2

ty. Water is present in joint planes and locally in fault planes. Table 33 gives a summary of hydrologic characteristics of the Wissahickon Formation. Table 34 gives the cumulative frequency distributions of well depths, depths of well casings, depths to water, yields, and specific capacities for wells completed in the Wissahickon Formation.

The reported depths of wells in the Wissahickon Formation range from 43 to 675 feet below land surface; the median is 187 feet. This is the greatest median depth of any of the major water-bearing rock units in Delaware County. More than 25 percent of the wells are deeper than 272 feet, and only 10 percent are less than 93 feet deep.

The reported depths of casings for wells in the Wissahickon Formation range from 4 to 127 feet below land surface, and the median is 40 feet. Although the maximum depth of casing is 127 feet, only 10 percent of well-casing depths are 70 feet or more below land surface.

The depths to water for wells in the Wissahickon Formation range from 1 to 85 feet below land surface; the median is 20 feet. Only 10 percent of the

Table 34. *Cumulative Frequency Distributions of Reported Well Depths, Depths of Well Casings, Depths to Water, Yields, and Specific Capacities for Wells in the Wissahickon Formation*

Hydrologic characteristic	Number of wells	90 percent <sup>1</sup>	75 percent <sup>1</sup>	50 percent <sup>1</sup>	25 percent <sup>1</sup>	10 percent <sup>1</sup>
Depth of well (feet)	133	93	122	187	272	451
Depth of well casing (feet)	114	21	30	40	49	70
Depth to water (feet)	112	6	11	20	35	50
Yield (gal/min)	127	5	10	20	40	65
Specific capacity [(gal/min)/ft]	72	.02	.06	.20	.45	.97

<sup>1</sup>Percentage of wells in which indicated value is equaled or exceeded.

depths to water are 50 feet or more below land surface, and 25 percent of the depths to water are less than 11 feet.

The yields of wells in the Wissahickon Formation range from 1 to 300 gal/min; the median yield is 20 gal/min. This is the highest median yield of the crystalline rock units in the county. The Wissahickon Formation has the greatest potential for providing a high-yielding well. Most of the water-bearing zones are penetrated within 300 feet of the land surface (Table 16). More than 90 percent of wells drilled in the Wissahickon Formation should provide 5 gal/min or more, which is adequate for domestic-supply purposes.

The specific capacities of wells in the Wissahickon Formation range from 0.004 to 2.9 (gal/min)/ft, and the median is 0.2 (gal/min)/ft. Except for the largest values, these specific capacities are similar to those of the granodioritic and felsic gneiss and mafic gneiss.

The probability of obtaining high yields is increased by locating wells in valleys or draws and by situating wells to take advantage of directions of groundwater flow due to schistosity. Wells can be expected to yield 20 gal/min and can yield up to 60 gal/min if properly located and developed.

### Quality of Water

Water-quality data for wells in the Wissahickon Formation are summarized in Table 35. The hardness ranges from 17 to 220 mg/L; the median is 68 mg/L.

Table 35. Summary of Water-Quality Data for Wells in the Wissahickon Formation

(Quantities are in milligrams per liter unless otherwise indicated)

Parameter	Number of samples	Range	Median
Hardness (as calcium carbonate)	62	17–220	68
pH (units)	58	5.4–8.0	6.4
Specific conductance ( $\mu\text{mho/cm}$ )	64	55–2,200	220
Nitrate (as nitrogen)	14	<10–6.7	1.1
Calcium	14	12–130	32
Magnesium	14	4.5–62	8.6
Sodium	14	4.8–98	21
Potassium	14	1.0–12	3.8
Chloride	14	4.8–650	40
Sulfate	14	12–94	42
Total dissolved solids	14	80–1,600	230
Iron ( $\mu\text{g/L}$ )	14	6–120,000	180
Lead ( $\mu\text{g/L}$ )	12	<1–11	3
Manganese ( $\mu\text{g/L}$ )	13	<1–13,000	100
Nickel ( $\mu\text{g/L}$ )	12	1–13	2

All but four samples from the Wissahickon Formation can be classified as soft to moderately hard.

The pH of water from wells in the Wissahickon Formation ranges from 5.4 to 8.0, and the median is 6.4. Although 8.0 is the highest pH measured in all the samples from the county, most of the samples from the Wissahickon Formation are acidic. Specific conductance ranges from 55 to 2,200  $\mu\text{mho/cm}$ ; the median is 220  $\mu\text{mho/cm}$ . Seventeen of 64 samples have specific conductances greater than or equal to 300, indicating large amounts of dissolved constituents.

The Wissahickon Formation has the highest concentrations of sodium, which range from 4.8 to 98 mg/L and have a median value of 21 mg/L. Chloride concentrations range from 4.8 to 650 mg/L, and the median is 40 mg/L; these are the highest chloride concentrations in the county. Only two samples analyzed from the Wissahickon Formation have concentrations of chloride greater than the USEPA MCL of 250 mg/L. These concentrations are probably indicative of site-specific contamination resulting from human activities. Total dissolved solids range from 80 to 1,600 mg/L, and the median is 230 mg/L. Only one sample exceeded the USEPA SMCL of 500 mg/L for dissolved solids.

The water from 14 wells in the Wissahickon Formation was analyzed for trace-metal concentrations. Iron concentrations range from 6 to 120,000  $\mu\text{g/L}$ ; the median is 180  $\mu\text{g/L}$ . Six of 14 samples analyzed for iron exceed the USEPA SMCL of 300  $\mu\text{g/L}$ . Manganese concentrations range from 2 to 13,000  $\mu\text{g/L}$ , and the median is 100  $\mu\text{g/L}$ . Nine of 13 analyses for manganese exceed the USEPA SMCL of 50  $\mu\text{g/L}$ .

## SUMMARY

Delaware County lies mostly in the Piedmont physiographic province in southeastern Pennsylvania. The landscape is characterized by gently rolling hills and is drained by six major streams that flow from northwest to southeast following the general slope of the land. Five of these, Cobbs Creek, Darby Creek, Crum Creek, Ridley Creek, and Chester Creek drain to the Delaware River estuary. Brandywine Creek, after it enters the state of Delaware, flows to the Christina River, which flows to the estuary.

Precipitation is the source of both surface water and groundwater. Although long-term average monthly precipitation is fairly evenly distributed throughout the year, evapotranspiration and variations in the type of precipitation reduce the groundwater recharge during the late spring and summer months, while in-

creasing direct runoff to streams. Groundwater discharges to the streams as base flow. The average annual precipitation is 43.46 inches per year and the total estimated storage of the groundwater reservoir is about 30 inches.

The county is adequately supplied with water by the existing public water utilities. Almost 62 percent of the water supplied by these purveyors is imported from groundwater and surface-water sources outside the county.

Five major crystalline rock units and one unconsolidated unit underlie the county. Of the crystalline units, anorthositic gneiss yields too little water for industrial or public water supply. Three others, the granodioritic and felsic gneiss, the mafic gneiss, and the ultramafite, yield only small quantities of water. The Wissahickon Formation is the most productive crystalline rock unit; the median well yield of the Wissahickon is about 20 gal/min. Elevated manganese and iron concentrations in water from wells in the Wissahickon Formation limit its use for some industrial purposes.

The informally named Trenton gravel consists of unconsolidated sediments. Although short-term potential yields of this unit are high, the shallowness of the deposits and the possibility of salt-water intrusion from the Delaware River limit its use for public or large industrial supply.

Wells yielding 10 to 20 gal/min are possible in most areas. The probability of obtaining the highest yields generally is increased by locating wells in valleys or draws. The probability of obtaining high yields decreases with depth and relatively few water-bearing zones are penetrated at depths of more than 300 feet below land surface. The direction of groundwater flow, regional faulting, and depth of water-bearing zones in nearby wells also should be considered to insure maximum yields. Groundwater quality in the county is generally suitable for human consumption and most uses except where site-specific contamination has degraded the quality.

## GLOSSARY

- Aquifer.** A formation, group of formations, or a part of a formation that contains sufficient saturated, permeable material to yield usable quantities of water to wells and springs.
- Base flow.** Discharge entering stream channels as effluent from the groundwater reservoir; the fair-weather flow of streams.
- Cubic feet per second.** The discharge of a stream of rectangular cross section, 1 foot wide and 1 foot deep, whose velocity is 1 foot per second.
- Direct runoff.** The water that moves directly over the land surface to streams promptly after rainfall or snowmelt.
- Discharge, groundwater.** The process by which water is removed from the saturated zone; also the quantity of water removed.
- Discharge, surface water.** The volume of water (or more broadly, the volume of fluid plus suspended sediment) that passes a given point within a given period of time.
- Drawdown.** The lowering of the water table or potentiometric surface caused by pumping (or artesian flow).
- Evapotranspiration.** Water withdrawn from a land area by direct evaporation and by plant transpiration.
- Formation.** A fundamental unit in rock stratigraphic classification. It is a body of rock characterized by uniform rock characteristics; it is generally tabular and is mappable at the earth's surface, or traceable in the subsurface through borings.
- Fracture.** A break in rocks along which no displacement has occurred.
- Hardness.** A chemical property of water, caused mostly by the presence of calcium and magnesium, which increases the amount of soap needed to produce lather. Water having a hardness (calculated as milligrams per liter of calcium carbonate) less than 60 is soft; between 61 and 120 is moderately hard; between 121 and 180 is hard; and greater than 180 is very hard. Field-determined values reported in grains per gallon were converted to milligrams per liter by multiplying by 17.1.
- Head, static.** The height above a standard datum of the surface of a column of water that can be supported by the static pressure.
- Hydraulic gradient.** Change in static head per unit of distance in a given direction.
- Hydrograph.** A graph showing depth, flow, velocity, or other characteristics of water with respect to time.
- Permeability.** The capacity of a material to transmit a fluid.
- pH.** The negative logarithm of the hydrogen-ion activity. A pH of 7.0 indicates a neutral solution; values higher than 7.0 denote alkaline solutions; values lower than 7.0 indicate acidic solutions.
- Porosity.** The ratio of the total volume of openings in a rock to the total volume of the rock, expressed as a percentage.
- Potentiometric surface.** The surface that represents the static groundwater head; the potentiometric surface for an unconfined aquifer is the water table.
- Primary porosity.** Porosity due to openings or voids within the rock when it was formed. In sedimentary rocks, openings result from the arrangement and nature of the original sediment.
- Recharge, groundwater.** The process by which water is added to the saturated zone; also the quantity of water added.
- Rock unit.** Any mass of bedrock or unconsolidated material that has been mapped as an entity and

given a name; rock units have characteristic features that permit them to be separated from other rock units.

**Runoff.** That part of the precipitation that appears in streams. It is the same as streamflow unaffected by artificial diversions, storage, or other works of man in or on the stream channels.

**Saturated zone.** The zone in which interconnected openings are saturated with water.

**Secondary porosity.** Porosity due to voids produced in rocks, subsequent to their formation, by solution, weathering, or movement.

**Specific capacity.** The yield of a well divided by the drawdown necessary to produce this yield; expressed as gallons per minute per foot of drawdown.

**Specific conductance.** A measure of the ability of water to conduct an electrical current; conductance increases with increasing concentration of dissolved minerals.

**Specific yield.** The ratio of the volume of water that a saturated rock or soil will yield when drained by gravity to the volume of rock or soil.

**Stream basin.** An area that is drained by a stream and all of its tributaries.

**Strike.** The compass bearing of a horizontal line in the plane of an inclined surface.

**Streamflow.** The actual flow in streams, whether or not subject to regulation, or underflow.

**Stream-gaging station.** A gaging station where a record of discharge of a stream is obtained. Within the U.S. Geological Survey this term is used only for those gaging stations where a continuous record of discharge is obtained.

**Surface water.** Water on the surface of the earth.

**Transpiration.** The process by which vapor escapes from the living plant, principally the leaves, and enters the atmosphere.

**Water table.** The upper surface of an unconfined subsurface water body where the pressure is equal to that of one atmosphere.

**Water year.** The 12-month period of time beginning on October 1 and ending on September 30, designated by the calendar year in which it ends.

## FACTORS FOR CONVERTING INCH-POUND UNITS TO INTERNATIONAL SYSTEM UNITS (SI)

<i>Multiply inch-pound units</i>	<i>By</i>	<i>To obtain SI units</i>
<i>Length</i>

Table 40. Record

Well location: The number is that assigned to identify the well. It is prefixed by the two-letter abbreviation of the county. The lat-long is the coordinates, in degrees, minutes, and seconds, of the well.

Use: C, commercial; E, power; F, fire; H, domestic; I, irrigation; N, industrial; P, public supply; R, recreation; T, institution; U, unused.

Topographic setting: F, flat; H, hilltop; S, hillside; T, terrace; V, valley; W, upland draw.

Aquifer: Qt, Trenton gravel; wan, anorthositic gneiss; gr, granodioritic gneiss; wb, wp, Wissahickon Formation; wbma, wma, pma, mafic gneiss, hornblende-bearing; wmg, mafic gneiss, pyroxene-bearing; wum, ultramafite; Ybfa, Proterozoic Y felsic gneiss, hornblende-bearing; Ybfg, Proterozoic Y felsic gneiss, pyroxene-bearing; Ybma, Proterozoic Y mafic gneiss, hornblende-bearing; Ybmg, Proterozoic Y mafic gneiss, pyroxene-bearing.

## of Selected Wells

Lithology: gn, gneiss; phy, phyllite; sch, schist; ser, serpentinite; sg, sand and gravel.

Static water level: Date measured—month/last two digits of year.

Reported yield: gal/min, gallons per minute.

Specific capacity: (gal/min)/ft—gallons per minute per foot of drawdown.

Hardness: mg/L, milligrams per liter.

Specific conductance:  $\mu\text{mho/cm}$  at 25°C, micromhos per centimeter at 25 degrees Celsius.

Total depth below land surface (feet)	Casing		Depth(s) to water-bearing zone(s) (feet)	Static water level		Reported yield (gal/min)	Specific capacity [(gal/min)/ft]	Hardness (mg/L)	Specific conductance ( $\mu\text{mho/cm}$ at 25°C)	pH (units)	Well number
